BRUCELLOSIS (brew′sell ōsis′) a specific contagious disease primarily affecting cattle, swine, and goats. It is characterized by abortions.

CONTAGIOUS (kŏn ta′ jus) spreading from one to another by direct or indirect contact with the disease.

CRESOL (krē′sōl) a substance derived from coal and wood tar, used as a disinfectant.

CARBOLIC ACID (kär bŏl′ ik) a weak acid derived from coal tar; also called phenol.

DEBRIS (de brē′) rubbish, waste material, dirt.

DIAGNOSIS (di′ăg nō′ sĭs) the process of identifying a disease by examination and study of its symptoms.

DISINFECTANT (dis′ in fekt′ ant) an agent, as carbolic acid or lime, used to destroy pathogens.

DISTEMPER (dis temp′ er) a highly contagious disease of dogs.

FORMALDEHYDE (for mal′ dĕ hīd) a colorless gas with a sharp odor, formed by partly burning methanol.

HEMORRHAGE (hem′ ō rij) any escape or discharge of blood from the blood vessels.

HEPATITIS (hep′ a tīt′ is) an acute infectious contagious disease of dogs, affecting primarily the liver.

HYPOCHLORITE (hīp ō clŏr′ īt) a salt of hypochlorus acid, used as an oxidizing agent. (Commercial bleaches are hypochlorites.)

INFECTIOUS DISEASE (in fek′ shŭs) any disease caused by the entrance and growth of pathogens in the body.

INSECT (ĭn′ sekt) any of a class of small animals whose bodies appear to have three distinct regions (head, thorax, abdomen), with three pairs of legs and usually winged.

28.144x

Figure 18-36.—Morse taper socket gage and plug gage.

are used to increase mechanical advantage and to provide good clamping ability as in the screw jack or vise screw.

Terminology

There are several terms used in describing screw threads and screw thread systems which you must know before you can calculate and machine screw threads. Figure 18-37 illustrates the application of some of the following terms:

External Thread.—A thread on the external surface of a cylinder.

Internal Thread.—A thread on the internal surface of a hollow cylinder.

Right-Hand Thread.—A thread which, when viewed axially, winds in a clockwise and receding direction.

Left-Hand Thread.—A thread which, when viewed axially, winds in a counterclockwise and receding direction.

Lead.—The distance a threaded part moves axially in a fixed mating part in one complete revolution.

Pitch.—The distance between corresponding points on adjacent threads.

Single Thread.—A single (single start) thread having the lead equal to the pitch.

Multiple Thread.—A multiple (multiple start) thread has a lead which is equal to the pitch multiplied by the number of starts.

Class of Threads.—Classes of threads are distinguished from each other by the amount of tolerance or tolerance and allowance specified.

Thread Form.—The axial plane profile of a thread for a length of one pitch.

Flank.—The side of the thread.

Crest.—The top of the thread (bounded by the major diameter on external threads; by the minor diameter on internal threads).

28.145

Figure 18-37.—Screw thread nomenclature.

S322661

Root.—The bottom of the thread (bounded by the minor diameter on external threads; by the major diameter on internal threads).

Thread Angle.—The angle formed by adjacent flanks of a thread.

Major Diameter.—The diameter of a cylinder that bounds the crest of an external thread or the root of an internal thread.

Minor Diameter.—The diameter of a cylinder that bounds the root of an external thread or the crest of an internal thread.

Height of Thread.—The distance from the crest to the root of a thread measured perpendicular to the axis of the threaded piece (also called depth of thread).

Slant Depth.—The distance from the crest to the root of a thread measured along the angle forming the side of the thread.

Thread Series.—Groups of diameter pitch combinations which are distinguished from each other by the number of threads per inch to a specific diameter. The common thread series are the coarse series and the fine series.

Forms of Threads

V-FORM THREADS.—The three forms of V-threads are the V-sharp, the American National and the American Standard. All of these threads have a 60° included angle between their sides. The V-sharp thread has a greater depth than the others and the crest and root of this thread have little or no flat. The external American Standard thread has slightly less depth than the external American National thread but is otherwise similar. The American Standard thread is actually a modification of the American National thread. This modification was made so that a unified series of threads, which permits interchangeability of standard threaded fastening devices manufactured in the United States, Canada, and the United Kingdom, could be included in the threading system used in the United States. The Naval Ship Systems Command and naval procurement activities use American Standard threading system specifications whenever possible; this system is recommended for use by all naval activities.

To cut a V-form screw thread, you need to know (1) the pitch of the thread, (2) the straight depth of the thread, (3) the slant depth of the thread, and (4) the width of the flat at the root of the thread. The pitch of a thread is the basis for calculating all other dimensions and is equal to 1 divided by the number of threads per inch. Twice the straight depth of an internal thread subtracted from the outside diameter of the externally threaded part is the basis for determining the bore diameter of a mating part to be threaded internally. When the thread cutting tool is fed into the workpiece at one-half of the included angle of the thread, the slant depth is the dimension necessary to determine how far to feed the tool into the work. The point of the threading tool must have a flat equal to the width of the flat at the root of the thread (external or internal thread, as applicable). If the flat at the point of the tool is too wide, the resulting thread will be too thin if the cutting tool is fed in the correct amount. If the flat is too narrow, the thread will be too thick.

The following formulas will provide you with the information you need to know for cutting V-form threads:

V-SHARP THREAD.

Pitch $= \frac{1}{n} = 1 \div$ number of threads per inch

Depth of thread = 0.866 x pitch = 0.866p

Slant depth of thread = pitch

AMERICAN NATIONAL THREAD.

Pitch = 1 ÷ number of threads per inch $= \frac{1}{n}$

Depth of external thread = 0.64952 x pitch = 0.64952p

Depth of internal thread = 0.541266 x pitch = 0.541266p

Width of flat at point of tool for external and internal threads = 0.125 x pitch = 0.125p

Slant depth of external thread = 0.750 x pitch = 0.750p

Slant depth of internal thread = 0.625 x pitch = 0.625p

AMERICAN STANDARD THREAD.

Pitch = 1 ÷ number of threads per inch $= \frac{1}{n}$

1082662

Depth of external thread = 0.61343 x pitch = 0.61343p
Depth of internal thread = 0.541266 x pitch = 0.541266p
Width of flat at point of tool for external threads = 0.166 x pitch = 0.166p
Width of flat at point of tool for internal threads = 0.125 x pitch = 0.125p
Slant depth of external thread = 0.708 x pitch = 0.708p
Slant depth of internal thread = 0.625 x pitch = 0.625p

To produce the correct thread profile, the cutting tool must be accurately ground to the correct angle and contour. Also the cutting tool must be set in the correct position. Figure 18-38 shows how a tool must be ground and set.

The point of the tool must be ground to an angle of 60°, as shown in A of figure 18-38. A center gage or a thread-tool gage is used for grinding the tool to the exact angle required. The top of the tool is usually ground flat, with no side rake or back rake. However, for cutting threads in steel, side rake is sometimes used.

The threading tool must be set square with the work, as shown in B and C of figure 18-38. The center gage is used to adjust the point of the threading tool and if the tool is carefully set, a perfect thread will result. Of course, if the threading tool is not set perfectly square with the work, the angle of the thread will be incorrect.

For cutting external threads, the top of the threading tool should be placed exactly on center as shown in D of figure 18-38. Note that the top of the tool is ground flat and is in exact alignment with the lathe center. This is necessary to obtain the correct angle of the thread.

Size of the threading tool for cutting an internal thread is important. The tool head must be small enough to be backed out of the thread and still leave enough clearance to be drawn from the threaded hole without injuring the thread. However, the boring bar which holds the threading tool for internal threading should be as large in diameter and as short as possible to prevent springing.

THE ACME SCREW THREAD.—The Acme screw thread is used on valve stems, the lead screw of a lathe, and other places where a strong thread is required. The top and bottom of the threads are similar to a square thread

28.146x

Figure 18-38.—Threading tool setup for V-form threads.

12663

in that they are flat. The sides of the thread have an included angle of 29° (fig. 18-39).

Parts A and B of figure 18-40 show the method of setting an Acme threading tool for cutting an external and internal Acme thread, respectively. Note that a 29° Acme thread gage is used in the same manner as the center gage was used for V-form screw threads. Adjust the cutting edge of the tool to line it up exactly with the beveled edge of the gage.

In cutting an Acme thread, there should be a clearance of 0.010 inch between the top of the thread of the screw and the bottom of the thread of the nut in which it fits.

THE SQUARE THREAD.—The square thread (fig. 18-41) is used where heavy threads are required, such as in jack screws, press screws, and feed screws. It is used for much the same purpose as the Acme thread, which is used in many places where the square thread was formerly used. The disadvantage of square threads is that the straight sides eliminate side-play adjustment.

The cutting edge width of the tool for cutting square screw threads is exactly one-half the pitch, but the width of the edge of the tool for threading nuts is from 0.001 inch to 0.003 inch larger. This permits a sliding fit on the screw.

The threading tool for cutting square threads is set square with the work. Since the edge of the tool is square, it is only necessary to adjust the edge to the surface of the work.

FORMULAS

$$\text{PITCH (P)} = \frac{1}{\text{No. Threads per inch}}$$

DEPTH (D) = 1/2 P + 0.010"
SLANT DEPTH = 0.516 P + 0.010"
CREST (C) = 0.3707 P
ROOT (R) = 0.3707 P − 0.0052"

28.147x

Figure 18-39.—Acme thread and formulas.

28.148x

Figure 18-40.—Use of Acme thread tool gage.

FORMULAS

$$\text{PITCH (P)} = \frac{1}{\text{No. Threads per inch}}$$

DEPTH (D) = P x 0.500"
SPACE (F) = P x 0.500"

28.149x

Figure 18-41.—Square thread and formulas.

The clearance between the top of the thread of the screw and that of the bottom of the thread of the nut should be about 0.005 inch to 0.006 inch for each inch of thread diameter.

Cutting Screw Threads

Cutting screw threads on the lathe is accomplished by connecting the headstock spindle of the lathe with the lead screw by a series of gears so that a positive carriage feed is obtained, and the lead screw is driven at the required speed with relation to the headstock spindle. The gearing between the headstock spindle and lead screw may be arranged so that any desired pitch of the thread may be cut. For example, if the lead screw has 8 threads per inch and the gears are arranged so that the headstock spindle revolves four times while the lead screw revolves once, the thread cut will be four times as fine

12664

as the thread on the lead screw, or 32 threads per inch. By means of the quick-change gear box, the proper gearing arrangement can be made quickly and easily by placing the levers as indicated on the index plate for the thread desired.

When the lathe is set up to control the carriage movement for cutting the desired thread pitch, the next consideration is shaping the thread. The cutting tool is ground to the shape required for the form of the thread to be cut, that is V, Acme, square, etc. The depth of the thread is obtained by adjusting the cross slide.

MOUNTING WORK IN THE LATHE.—When mounting work between lathe centers for cutting screw threads, be sure the lathe dog is securely attached before starting to cut the thread. If the dog should slip, the thread will be ruined. Never remove the lathe dog from the work until the thread has been completed. If it is necessary to remove work from the lathe before the thread is completed, be sure that the lathe dog is replaced in the same slot of the driving plate.

When threading work in the lathe chuck, be sure the chuck jaws are tight and the work is well supported. The chuck must be tight enough on the spindle to prevent unscrewing when the lathe is reversed. Never remove the work from the chuck until the thread is finished.

When threading long slender shafts, use a follower rest. The center rest must be used for supporting one end of long work that is to be threaded on the inside.

POSITION OF COMPOUND REST FOR CUTTING SCREW THREADS.—Ordinarily on threads of fine lead, the tool is fed straight into the work on successive cuts. For coarse threads, it is better to set the compound rest at one-half of the included angle of the thread and feed in along the side of the thread. For the last few finishing cuts, the tool should be fed straight in with the crossfeed of the lathe to make a smooth, even finish on both sides of the thread.

When cutting V-form threads and when maximum production is desired, it is customary to place the compound rest of the lathe at an angle of 29°, as shown in part A of figure 18-42. When the compound rest is set in this position, and the compound-rest screw is used for adjusting the depth of cut, most of the metal is removed by the left side of the threading tool

28.150x

Figure 18-42.—Compound rest set at 29°.

(part B of fig. 18-42). This permits the chip to curl out of the way better than if the tool is fed straight in, and prevents tearing the thread. Since the angle on the side of the threading tool is 30°, the right side of the tool will shave the thread smooth and produce a better finish; although it does not remove enough metal to interfere with the main chip, which is taken by the left side of the tool.

USING THE THREAD-CUTTING STOP.—On account of the lost motion caused by the play necessary for smooth operation of the change gears, lead screw, half-nuts, etc., the thread-cutting tool must be withdrawn quickly at the end of each cut. If this is not done, the point of the tool will dig into the thread and may be broken off.

To reset the tool accurately for each successive cut, and to regulate the depth of the chip, the thread-cutting stop is useful.

First, set the point of the tool so that it just touches the work, then lock the thread-cutting stop and turn the thread-cutting stop screw A (fig. 18-43) until the shoulder is tight against stop B (fig. 18-43). When ready to take the first chip, run the tool rest back by turning the crossfeed screw to the left several times and move the tool to the point where the thread is to start. Then turn the crossfeed screw to the right until the thread-cutting stop screw strikes the thread-cutting stop. The tool is now in the original position, and turning the compound-rest feed screw in 0.002 inch or 0.003 inch will place the tool in a position to take the first cut (fig. 18-43).

For each successive cut after the carriage is returned to its starting point, the tool can be reset accurately to its previous position. Turn

12665

the crossfeed screw to the right until the shoulder of screw A strikes stop B. Then the depth of the next cut can be regulated by adjustment of the compound rest feed screw as for the first chip.

28.151x

Figure 18-43.—Adjustable thread-cutting stop mounted on carriage saddle (clamped to dovetail).

For cutting an internal thread, the adjustable thread-cutting stop should be set with the head of the adjusting screw on the inside of the stop. In this case, the tool is withdrawn by moving it toward the center or axis of the lathe.

The micrometer collar on the crossfeed screw may be used in place of the thread-cutting stop, if desired.

To do this, first bring the point of the threading tool up so that it just touches the work; then adjust the micrometer collar on the crossfeed screw to zero. All adjustments for obtaining the desired depth of cut should be made with the compound-rest screw. Withdraw the tool at the end of each cut by turning the crossfeed screw to the left one complete turn; return the tool to the starting point and turn the crossfeed screw to the right one turn, stopping at zero. The compound rest feed screw may then be adjusted for any desired depth.

ENGAGING THE THREAD FEED MECHANISM.—When threads are being cut on a lathe, the half-nuts are clamped over the lead screw to engage the threading feed and released at the end of the cut by means of the threading lever. The threading dial (illustrated in fig. 18-15) provides a means for determining the time to engage the half-nuts so that the cutting tool follows the same path during each cut. When an index mark on the threading dial is aligned with the witness mark on its housing, the half-nuts may be engaged. For some thread pitches however, the half-nuts may be engaged only when certain index marks are aligned with the witness mark. On most lathes the half-nuts can be engaged as follows:

For all even-numbered threads per inch, close the half-nuts at any line on the dial.

For all odd-numbered threads per inch, close the half-nuts at any numbered line on the dial.

For all threads involving one-half of a thread in each inch, such as 11 1/2, close the half-nuts at any odd-numbered line.

CUTTING THE THREAD.—After setting up the lathe, as explained previously, take a very light trial cut just deep enough to scribe a line on the surface of the work, as shown in part A of figure 18-44. The purpose of this trial cut is to be sure that the lathe is arranged for cutting the desired pitch of thread.

28.152x

Figure 18-44.—The first cut.

To check the number of threads per inch, place a rule against the work, as shown in part B of figure 18-44, so that the end of the rule rests on the point of a thread or on one of the scribed lines. Count the scribed lines between the end of the rule and the first inch mark, and this will give the number of threads per inch.

It is quite difficult to count accurately fine pitches of screw threads, as described above. A screw pitch gage used as illustrated in figure 18-45 is very convenient for checking the finer screw threads. This gage consists of a number of sheet metal plates in which are cut the exact form of threads of the various pitches and each plate is stamped with a number indicating the number of threads per inch for which it is to be used.

28.153x

Figure 18-45.—Screw pitch gage.

Final check for both diameter and pitch of the thread may be made with the nut that is to be used or with a ring thread gage, if one is available. The nut should fit snugly without play or shake but should not bind on the thread at any point.

RESETTING THE TOOL.—If the thread-cutting tool needs resharpening or gets out of alignment, or if you are chasing the threads on a previously threaded piece, you must reset the tool so that it will follow the original thread groove. This may be done by using the compound-rest feed screw and crossfeed screw to jockey the tool to the proper position, by disengaging the change gears and turning the spindle until the tool is positioned properly, or by loosening the lathe dog (if used) and turning the work until the tool is in proper position with the thread groove. In either case the micrometer collars on the crossfeed screw and compound rest screw will usually have to be reset.

Before adjusting the tool in the groove, use the appropriate thread gage to set the tool square with the workpiece. Then with the tool a few thousandths of an inch away from the workpiece, start the machine and engage the threading mechanism. When the tool has moved to a position such as is shown in figure 18-46, stop the lathe without disengaging the thread mechanism.

The most practical and commonly used method for resetting a threading tool for machining angular form threads is the compound rest and crossfeed positioning method. By adjusting the compound rest slide forward or backward the tool is moved parallel to the axis of the work as well as toward or away from the work. When the point of the tool coincides with the original thread groove (see alternate view of tool in fig. 18-46), the crossfeed screw is used to bring the tool point directly into the groove. When a good fit between the cutting tool and thread groove is obtained, the micrometer collar on the crossfeed screw is set on zero and the micrometer collar on the compound rest feed screw is set to the depth of cut previously taken or to zero as required. (Note: Be sure that the thread mechanism is engaged and the tool is set square with the work before adjusting the position of the tool along the axis of the workpiece.)

If it is inconvenient to use the compound rest for readjusting the threading tool, the lathe dog (if used) may be loosened; turn the work so that threading tool will match the groove, and tighten the lathe dog. If possible, however, avoid the necessity of doing this.

Another method that is sometimes used, is to disengage the reverse gears or the change gears; turn the headstock spindle until the point of the threading tool enters the groove in the work, and then engage the gears.

FINISHING THE END OF A THREADED PIECE.—The end of a thread may be finished by any one of several methods. The 45° chamfer on the end of a thread, as shown in part A of figure 18-47, is commonly used for bolts, and cap screws. For machined parts and special screws,

28.154x

Figure 18-46.—Tool must reset to original groove.

28.155x

Figure 18-47.—Finishing the end of a threaded piece.

8332667

the end is often finished by rounding with a forming tool, as shown in part B of figure 18-47.

It is difficult to stop the threading tool abruptly, so some provision is usually made for clearance at the end of the cut. In part A of figure 18-47, a hole has been drilled at the end of the thread, and in part B, a neck or groove has been cut around the shaft. The groove is preferable, as the lathe must be run very slowly in order to obtain satisfactory results with the drilled hole.

ISOLATION (ī sōl′ā′shun) act of isolating, i.e., keeping an animal separate from the herd.

LETHAL (lē′thal) deadly, fatal.

LEPTOSPIROSIS (lep′tō spī rō′sis) an acute infectious disease caused by a spyrochete. Man, dogs, cattle, pigs, and horses are susceptible.

LYE (lī) a strong alkali substance composed chiefly of potassium carbonate. Used as a disinfectant.

MALNUTRITION (mal′nu trĭsh′un) an unhealthy condition resulting either from poor feed or lack of feed.

ORGANISM (ōrg′an ĭzm) any living being.

PARASITIC (par′a sĭt′ik) referring to a disease caused by a parasite; designating a carrier of such disease.

PATHOGEN (păth′og jen) an organism capable of producing disease.

PHENOL (fēn′ol) see carbolic acid.

PUTREFACTION (pūt rē făk′shun) the decomposition of organic matter.

QUARANTINE (kwär′an tēn) a condition of isolation. The isolation of an animal with a contagious disease.

RABIES (rā′bees) an acute infectious disease of the central nervous system.

RODENT (rō′dent) pertains to the order of (rodentia) gnawing mammals, such as rats, mice and squirrels.

SANITATION (săn ĭ tā′shŭn) pertaining to health, the preservation or restoration of health.

STRESS (strĕs) unusual strain due to unfavorable conditions.

SUSCEPTIBLE (sŭ sep′ti bl) such in constitution or temperament to be unresistant; liable through weakness.

SYMPTOM (sĭmp′tum) any perceptible change in the body or its functions indicating disease.

TOXICITY (tŏks ĭs′ĭ tĭ) quality, state, or degree of being toxic or poisonous.

TRANSMISSIBLE (trans mĭs′i bl) capable of being transmitted, as through inheritance, contact, etc.

TRAUMATISM (trô′ma tĭs m) the morbid condition of the system due to wounds, injury or shock.

TUBERCULOSIS (tū bŭr′kū lō sis) an infectious disease caused by certain bacteria. Commonly found in the lungs.

VACCINATE (văk′si nāt) to innoculate with any vaccine as a preventive measure.

ABSTRACT - To assist the instructor in teaching the course, transistors and printed circuits, this teaching guide was developed by the Department of the Navy. Contents are: (1) Introduction to Transistors, (2) Semiconductor Basic Circuits, (3) Transistor Circuit Applications, (4) Printed Circuits, and (5) Description of Training Device Circuits. Also included are suggestions for the instructor, a training aid list, and a master materials list. (GB)

TRANSISTORS AND PRINTED CIRCUITS
INSTRUCTOR'S GUIDE, NAVPERS 92386A

1. This publication has been prepared to assist the instructor in teaching the course, Transistors and Printed Circuits. The Trainee's Guide, NavPers 92387A, the complementing text for this course, is designed for student use.

2. Corrections and recommended changes to this publication are invited. Commanding Officer, Service School Command, Great Lakes, Illinois, is hereby assigned clearing house responsibility for evaluating and compiling recommended improvements, and for submitting them to the Chief of Naval Personnel in the form of a proposed change to the publication. Users of this course material are requested to submit their recommendations directly to the Commanding Officer, Service School Command, Great Lakes, Illinois, with a copy to the Chief of Naval Personnel (Attn: Pers-C1).

3. This publication supersedes Transistors and Printed Circuits, Instructor's Guide, NavPers 92386 (1960).

HOW TO USE THIS INSTR

TECHNICAL TRAINING

This Instructor's Guide has been prepared to place emphasis on the practical training of the technician in the operation, adjustment, and maintenance of equipment which contains either transistors or printed circuits. All Navy Technicians are craftsmen - not engineers or designers - and they will learn their skill by doing.

PRACTICAL WORK

All theory discussions must be tied to practical work. The design theory of transistors and printed circuits may be interesting to you, but the trainee must primarily learn how to service transistors and printed circuits. The trainee must concentrate on learning to perform the necessary adjustment and maintenance techniques required by transistors and printed circuits. Any activity that does not contribute directly to training in the servicing of transistors and printed circuits is wasted effort, regardless of how interesting it may seem to be. The reason for having theory is to assist the trainee in doing practical work.

TRAINING GOALS

The trainee must understand the training goals for each topic. These goals and the skills to be acquired are stated in his Trainee's Guide. The mere statement is not sufficient. You must be certain that he understands the goals, so that he will know when he has attained them. The topic will have been completed when each trainee has attained every goal.

STUDY ASSIGNMENTS

Study assignments are provided in your Instructor's Guide and in the Trainee's Guide. Study assignments covering the

MF AVAILABLE IN VT-ERIC SET.
Service Bulletin Number Three
PUB DATE - Aug69 54p.

DESCRIPTORS - *SUPPLEMENTARY TEXTBOOKS; *VOCATIONAL AGRICULTURE; *PLANT SCIENCE; *PLANT PATHOLOGY; *RESOURCE MATERIALS

ABSTRACT - One of a series of service bulletins prepared to aid vocational agriculture teachers in presenting introductory material on specific areas of agricultural science, this booklet provides basic instruction on plant diseases. The unit is recommended for use in the second year of vocational agriculture, with major emphasis upon helping students to develop an understanding of basic principles and terminology related to plant pathology. Contents include: (1) Importance of Plant Diseases, (2) The Nature and Classification of Plant Diseases, (3) Growth and Reproduction of Plant Pathogens, (4) Dissemination of Plant Pathogens, (5) Infection by Plant Pathogens, and (6) Principles of Plant Pathology in Exercises and Experiments. A section giving descriptions and information on specific plant diseases, including various photographs and charts, is also provided, as well as a glossary, selected references for teachers and students, teaching aids and materials, films and slides, and suggested resource people. Other bulletins in the series are available as VT 001 012 and VT 001 013 (AIM Winter 1968) and VT 010 369, also in this issue. An instructor's guide for teaching this unit may be obtained from the Department of Agricultural Education, University of Arizona, Tucson. (AW)

S

e provided in your Instructor's Guide
. Study assignments covering the

material to be discussed the following day should normally be made at the end of the preceding school day.

DISCUSSION TOPICS AND TRAINING AIDS

After the trainee has studied the assigned material he is ready to engage in a discussion of the stated topics. It is your responsibility to guide the discussion so as to accomplish the learning goals. The use of training aids and demonstration of the equipment will facilitate learning. Where a skill is to be acquired, actual work on the equipment is necessary. You will demonstrate the correct techniques and the trainee will learn by doing. The transistor circuit training device will be the most important training aid used.

PRECAUTIONS FOR USE OF TRAINEE'S GUIDE

The Trainee's Guide is provided for the trainee's use while learning the theory, operation, and application of transistors and printed circuits, and is intended for his retention at the end of this course. A quantity of blank pages have been provided in the Trainee's Guide, and note-taking is to be encouraged by the instructor.

DIVISION OF COURSE MATERIAL INTO FUNCTIONAL SYSTEMS

The course material in the Instructor's Guide has been sectionalized according to the functional applications of the components to be studied. This arrangement is better adapted to teaching for understanding of the transistors and printed circuits to be used. Since the Trainee's Guide has been organized with the same progression and sequence of units, the study assignments will follow in an orderly manner.

STATE DEPARTMENT OF VOCATIONAL EDUCATION
412 Arizona State Building
Phoenix, Arizona 85007

Mrs. Sarah Folsom, Executive Officer, State Board for Vocational Education and Superintendent of Public Instruction

J. R. Cullison, Director, Vocational-Technical Education

Carlos H. Moore, State Supervisor, Agricultural Education

Gordon H. Hall, Assistant State Supervisor, Agricultural Education

MEMBERS OF STATE BOARD FOR VOCATIONAL EDUCATION
1965

Ex-Officio Member

The Honorable Sarah Folsom, Superintendent of Public Instruction

Members Appointed by the Governor

Dr. G. Homer Durham, Tempe -- Arizona State University

Dr. Taylor Hicks, Prescott -- State Junior College Board

Miss Jean Hansen, Tucson -- Classroom Teacher Representative

Miss Mary O'Brien, Florence -- Pinal County School Superintendent

Robert W. Taylor, Globe, Supt., High School District Representative

Louis McClennen, Phoenix -- Chairman of the Board -- Lay Member

James F. McNulty, Jr., Bisbee -- Vice President -- Lay Member

Mrs. Anna Margaret Osborn, Yuma -- Lay Member

DISCUSSION - DEMONSTRATION

Suggested Procedures:

DISCUSSION POINT	RELATED INSTRUCTOR ACTIVIT
1. Operation of the P-N junction.	1. Show Film MN 8479A.
a. Effects of bonding together N- and P-type material.	
b. Potential barrier.	
c. Formation of Germanium diode.	
2. Obtaining forward bias.	2. Demonstrate forward current using a Germanium or Silico diode. Use transparency 1-4-1.
a. Effects of connecting battery.	
3. Description of reverse bias.	3. Demonstrate reverse current using a Germanium or Silicon diode. Use transparency 1-4-1.
a. Current flow.	
b. Use as a rectifier.	
c. Description of Zener voltage.	
4. Description of Zener diode.	
a. Use as a voltage regulator.	
5. Review and summary.

TOPIC 5: OPERATION OF THE TRANSISTOR

Trainee Preparation:

A. Trainee's Guide:

1. Study Section 1, Topic 5.

Instructor Preparation:

A. Review materials to be presented.

B. Training aids required:

1. Film:

   a. MN 8479B, Transistors - Triode Fundamentals

2. Transparencies:

   a. 1-5-1, Vacuum Tube Triode and Transistor.

   b. 1-5-2, NPN Junction Transistor with Input Signal.

DISCUSSION-DEMONSTRATION-

Suggested Procedures:

DISCUSSION POINT	RELATED INSTRUCTOR ACTIVITY
1. Comparison of transistor and vacuum tube.	1. Project transparency 1-5-1.
a. Functions of emitter and cathode.	
b. Functions of base and grid.	
c. Functions of collector and plate.	
2. Types of junction transistors.	2. Show Film MN 8479B.
a. PNP junction transistor.	
b. NPN junction transistor.	
3. How junction transistors are manufactured.	
a. The alloy-junction transistor.	
b. The grown-junction transistor.	
4. Description of point-contact transistor.	
5. Tetrode transistors used for additional frequency response.

PREFACE

This publication is the third in a series of service bulletins prepared by the Department of Agricultural Education to attempt to meet the requests of Arizona vocational agriculture instructors for materials to teach introductory content on specific areas of agricultural science. The enthusiastic response to the first two publications, Harmful Parasites of Domestic Animals and An Introduction to Animal Diseases encouraged the preparation of this booklet on plant diseases.

The primary purpose of this publication is to provide basic general information on plant pathology and to guide students through experiences in the laboratory that will lead toward a better understanding of the various types of plant diseases and how those diseases affect plants. Information about specific plant diseases is included only to serve as examples of the various types of diseases that affect crops in Arizona. Additional references will be needed to supplement this publication when teaching units on the cause, symptoms, prevention and treatment of specific diseases.

It is suggested that this unit be taught in the second year of vocational agriculture and emphasis be given to developing an understanding of basic principles and terminology. The identification and control of specific plant diseases of commercial crops may be taught as a follow-up to this unit or integrated with the content on various crop production units. An instructor's guide for teaching this unit is available from the Department of Agricultural Education.

This publication is the product of the cooperative effort of many people, including Wayne Mortenson and Phil Neilson, graduate students in Agricultural Education, Phillip R. Zurbrick, Graduate Research Assistant in Agricultural Education and Dr. John R. Williams, Associate Professor of Agricultural Education. Dr. Alice M. Boyle and Dr. Arlen D. Davison of the Department of Plant Pathology evaluated and checked all content for accuracy and helped in preparing the laboratory exercises. Most of the descriptive sheets on specific diseases were prepared by Dr. Davison and Dr. Shields and made available through the Arizona Agricultural Extension Service. A preliminary edition of this publication was used on a trial basis in several departments of agriculture during the school year 1964-65 and was then further evaluated by members of the State Committee on Course Construction, composed of Carlos H. Moore, State Supervisor of Agricultural Education, Frank Adams, Page Bakarich, R. Clair Decker, Gordon G. Hall, Cy Henry, Richard Meder and Ronald Wolhart, all teachers of agriculture.

TOPIC 4: MISCELLANEOUS TRANSISTOR CIRC

Training Goals:

A. Each trainee will learn:

1. The nature and purpose of transistorized oscillator circuits.

2. The nature, construction, and operating characteristics of resonant circuits.

3. The nature and purpose of positive feedback circuits.

4. The construction, purpose of various components, and operation of some transistorized external feedback oscillators and their comparison with vacuum tube equivalents:

   a. The Armstrong Oscillator.

   b. The Hartley Oscillator.

   c. The Colpitts Oscillator.

5. The principle of negative resistance as it applies to the construction and operation of internal feedback oscillators.

6. The use of complementary symmetry transistor multivibrators.

7. The construction and operating characteristics of multivibrator circuits as compared with the vacuum tube equivalent.

IMPORTANCE OF PLANT DISEASES

Importance of Plants

Man is completely dependent upon the plant kingdom. His food, clothing, shelter and much of his fuel comes from plants. Plants alone are capable of synthesizing elementary substances into organic compounds necessary for animal metabolism and growth. Bacteria, fungi, mosses, ferns, and seed plants are included in the plant kingdom, the most important being the seed plants. Of the more than 200,000 species of plants, about 3,000 are used for food, only 300 are widely cultivated and of these some dozen plants supply 95 per cent of the world's annual food crop.

1. Economic Importance of Plant Diseases. Diseases may make plant products unfit for human or animal food. During the Middle Ages thousands of people died from eating rye bread made from grain infested with ergot, *Claviceps purpurea*. Scabby barley caused by *Gibberella zeae* makes pigs violently sick. Stinking smut of wheat caused by *Tilletia triticic* may require special washing of the grain before milling. Transportation and storage diseases cause losses in succulent fruits and vegetables. Even less perishable food such as rice, millet, and beans may be damaged by storage diseases. Wood products such as pulpwood, posts, poles, and timber are subject to fungus stains and structural weakness.

It is impossible to give accurate data on financial losses from plant diseases. The magnitude of such losses can be shown, however. A stem rust epidemic destroyed almost 300 million bushels of wheat in the United States and Canada in 1916. Not only was it ruinous to the crop, but it forced thousands of farmers from their farms through despair or bankruptcy. The reduction in the quality and price of the wheat harvested and marketed increased the loss still more. Moreover, the loss in purchasing power of farmers affected business in the entire spring-wheat region and far beyond. Each year cotton yields in Arizona are reduced by diseases. The estimated loss in dollars due to plant diseases in Arizona alone in 1963 was set at over $38,000,000. This estimate is considered conservative because not all crops were figured in the estimate. Cotton was the hardest hit with a total loss of over $21,000,000.

Plant diseases often force the substitution of low-value crops for high-value crops, the substitution of inferior varieties for superior ones, the limiting of land where a crop can be grown, and the loss of capital investment in processing plants and other equipment through non-use. One of the practical obligations of the plant pathologist is to attempt to control these devastating epidemics which can cause violent fluctuations in the production of the world's food crops. The price for this work is not low. The cost of capital investment in spray machinery, chemicals for treatment, labor, and the cost of large-scale eradication campaigns amount to millions of dollars each year. Another expense in the control of disease is the cost involved in developing new disease resistant crops.

2. Developments in the Study of Plant Diseases. Farmers have always been beset with hazards in their struggles to feed others. Plant diseases, insect pests, weeds, and unfavorable weather are among the greatest hazards. Frequent references in the Bible tell of famines caused by plant diseases and insects. The ancient Greeks thought that the occurrence of disease was due to unfavorable soil or weather and to the displeasure of the gods. Many of the ancient rites of the pagan religions were to gain favor of the gods in order to spare their crops from destruction. The first known attempt to control a plant disease was a law passed in Rouen, France in 1660, requiring the eradication of barberry bushes because of their apparent connection with the destructive rust on cereals. Similar laws were passed in Connecticut (1726), Massachusetts (1753), Rhode Island (1766-1772).

With the invention of the compound microscope about 1590, micro-organisms were first seen, but it took centuries before man began to understand them. The terrible potato blight that struck Ireland between 1830 and 1840 with the resultant migration of many millions to the United States added increased impetus to the study of plant diseases. De Bary, "the father of modern plant pathology," is usually credited with the discovery in 1850 that fungi can cause plant disease. Discovery that bacteria and viruses also cause plant diseases followed within a few decades. The improvement in materials and methods for disease control by chemicals, cultural practices, storage facilities and resistant varieties has come within the past thirty to fifty years. Plant diseases still take a heavy toll in all important agricultural areas, because known satisfactory control measures are not used as frequently as they should be and feasible methods for controlling some diseases have not been worked out.

THE NATURE AND CLASSIFICATION OF PLANT DISEASES

A plant disease may be defined as any alteration of a plant that interferes with its normal structure or function and renders it unfit for its normal use. Plant diseases are often classified by symptoms and causal agents.

Classification of Plant Diseases Based on Symptoms

One method of classification of plant disease is that based on symptoms. A symptom is a visible reaction of the plant to disease. Five common symptoms of plant disease are superficial, necrosis, hypoplasia, hypertrophy, and wilt.

1. Superficial diseases are those in which the organism lives on the surface of the plant tissue. They invade the epidermal cells of the plant with a haustoria (foot like organ) and cause reduction in thriftness in the whole plant which is reflected in reduced yield. Powdery mildew is an example of a superficial disease.

2. Necrosis is the destruction of tissue. It may be general when due to species of micro-organisms that grow as long as there is susceptible tissue. Necrosis is manifest as either dry rots or soft rots. An example of soft rot is lettuce watery brown rot. Commonly affected plant parts include fleshy organs such as fruits and bulbs. Timber, railroad ties, posts and poles may also be rotted. Dry rots may be

root rots, leaf spots, blights, cankers, scabs, or anthracnose. It is local in the case of leaf spots and fruit spots where the extent of the lesion is limited. Often the lesions are characteristic in shape, size, pattern and color. For example, necrosis occurring in the disease, angular leaf spot of cotton, is limited by veins of the leaf, thus being limited in shape and size.

3. Hypoplasia or underdevelopment is the stunting or dwarfing of a plant. It may be caused by a virus such as sugar beet yellows and mosaic dwarf of potatoes or it may be caused by a fungus such as dwarf bunt of wheat. Underdevelopment of above ground parts of plants may also result from destruction of roots, an excess of a deficiency of soil moisture and/or nutrients.

4. Hypertrophy or abnormal overgrowth, may be caused by some viruses, fungi, nematodes, bacteria, or insects. These may cause distortions, deformations and galls. Some chemicals including the "growth hormones," the growth modifiers, and the weed killer 2,4-D may also cause abnormal overgrowth. Some examples are corn smut galls, potato wart and cabbage club root.

5. Wilts are a loss of freshness and drooping of leaves of plants due to inadequate water supply through the vascular system. Plants with wilt symptoms usually show discoloration of the root and/or stem vascular system. Verticillium wilt of cotton is an example of a wilt disease.

Classification of Plant Diseases Based on Causal Agents

The two broad categories of causes or combination of causes of plant diseases are: inanimate or non-parasitic and animate or parasitic.

1. Inanimate or non-parasitic causal agent are terms used interchangeably to describe the cause of any unhealthy condition not brought about by a living organism. Many cases of weakened or unthrifty plants are due to soil conditions. Deficiency of soil moisture causes stunting, premature ripening and death in case of severe drought. Extensive and pronounced drought injury is clearly recognizable, but milder forms are sometimes difficult to diagnose, especially if plants are affected by parasitic diseases. Excess soil moisture causes indirect injury; the water itself is not usually injurious, but it can reduce the amount of oxygen to the danger point or even beyond. The physical structure of the soil may have a direct effect on plants if it is so hard and compact as to prevent normal penetration and development of roots. A hard pan near the soil surface prevents normal root growth. Heavy clay soils may prevent proper drainage; sandy or gravelly soils have poor water holding capacity. Both deficiency or an excess of a major or minor plant nutrient can cause disease symptoms. For example, a deficiency of nitrogen causes yellowish, reddish or purplish tints, subnormal growth and poor seed or fruit production. An excess of nitrogen causes succulent growth, delayed ripening and consequent increased susceptibility to diseases, heat and drought injury. Soil pH. has a decided effect upon plant growth. Most agriculture plants grow well in soils with a pH.

7. Review and summary.	

ranging from about 4 to 8. Excessive salt in the soil may also cause plants to become weakened or even die.

The presence of lime, as calcium carbonate may bring about an excess of hydroxyions around soil particles. Under these conditions in the soil, the elemental iron in soil solution is precipitated (become unavailable) and the roots fail to pick it up. Since iron is essential to the formation of chlorophyll, this lack causes the plant to become chloratic (yellow).

Many meteorologic conditions cause diseases directly and can also effect the development of parasitic diseases. All higher plants require sunlight for photosynthesis. Light deficiency causes etiolation, weak, spindly growth and general under-development. Alfalfa and oats require long days; soybeans need short days; other crops are indifferent. Certain varieties of a crop mature many weeks later than others, thus they are longer in jeopardy of damage from unfavorable weather and attack by diseases. Summer heat, winter cold and unseasonable frosts can injure or destroy a high percentage of crop plants even in areas where they are adapted. Tropical and sub-tropical plants are easily injured by frost, while crops in temperate climates are more resistant. Tomatoes are often "cooked on the vine" when high temperatures follow moist, cloudy weather. "Smudge pots" protect citrus against frost; heated greenhouses protect plants against winter cold.

Relative humidity of the air obviously has an effect on the rate of transpiration of plants. The combination of heat, wind and low relative humidity can cause extensive injury or death to plants. Wind, heavy rain, sleet, hail or lightening may cause direct or indirect injuries which reduce the vigor of the plant and provide avenues of entrance for parasitic organisms.

A farmer's cultural practices may injure plants. Too deep or too close cultivation may cause injury. Fungicides when improperly used may cause russeting of leaves and fruit, leaf and fruit drop and scorch. Insecticides may accumulate in the soil to cause injury to fruit trees. Herbicides such as 2,4-D may cause severe injury to plants at a susceptible stage.

Industrial contaminants such as dust from cement plants may settle on the floral parts and prevent fertilization and fruit formation. Smelter fumes, gas leaking from mains and even smog in large cities have caused extensive injury to plants. Volitile compounds given off by apples in storage may cause fruit scald.

2. Animate or parasitic causal agent are terms used to describe the cause of any unhealthy condition brought about by a living organism. Higher animals occasionally cause an unhealthy condition of plants that satisfies the definition of plant disease. For example, a farmer mowing a field of alfalfa does interfere with the normal structure and function of the alfalfa, but does not render it unfit for its normal use and so would not be called a disease. However, a cow that gets into the field of corn and tramps down or eats the corn plants does interfere with the normal structure and function of the corn and does

render it unfit for its intended use and would therefore be called an animate causal agent.

Insects such as leafhoppers, while feeding on a plant, secrete toxic substances which cause a diseased appearance, e.g. hopperburn of potatoes. Other insects cause overgrowths such as witchesbroom or plant galls.

Most animate causal agents are parasites, living organisms that obtain their nutrients wholly or in part from other living organisms, and so the term parasitic causal agent is often used interchangeably with animate causal agent.

Nematodes are very small roundworms, varying in size from 1/8 inch to so small they cannot be seen except through a microscope. Many are free living; others are parasitic on animals and plants. Nematodes may attack any part of a plant, including the roots, stems, leaves, flowers and fruit. Examples of diseases caused by nematodes are stem nematodes of alfalfa and rootknot nematode of cotton (See the individual disease section of this publication).

The majority of known plant parasites are bacteria or fungi. Bacterial plant pathogens are small, rod-shaped, single-celled micro-organisms 2 to 4 microns long (a micron is one-thousandth of a millimeter). Bacteria are the simplest form of plants. They are so tiny that if 8,000 to 12,000 were placed side by side they would not exceed an inch. (See colonies of bacteria collected in exercise two.) Even though bacteria are small and consist of only one cell, they multiply at an enormous rate. This increase in number is carried out by division. Redivision may vary from 20 minutes to several hours. In some of the faster multiplying types, a single bacterium could produce over 47,000,000,000 descendants in a 12 hour period. Fortunately, most bacteria are beneficial to mankind. Some cause human disease, however, and 170 different kinds of bacteria are capable of feeding on green plants and producing a disease condition. Bacteria cannot penetrate directly into plants. They must make entry through the breathing pores, wounds or be deposited by a feeding insect.

An example of a bacterium entering a plant by a wound is Agrobacterium tumefaciens which causes Crown Gall. An example of a bacterium that enters a plant by insects is Ervinia arnylovora, the cause of Fire Blight. (See individual disease section of this publication.)

Fungi are tiny, thread-like microscopic plants, commonly called molds. Fungi are living plants. They require a source of energy but, unlike green plants, cannot use energy from the sun to make their food. They must get food from external sources such as other plants. When these plant-feeding fungi become numerous, a disease epidemic develops. (See colonies of fungi collected in exercise two.) Many fungi reproduce by the formation of spores. These spores are produced on the tips of the filaments in or on specialized structures. Spores are produced in fantastic numbers,sometimes millions, on a single plant. Many never find lodging on a desirable host, but because spores are in such large numbers, reproduction continues. Under favorable conditions, a spore

landing on a susceptible plant can produce a new infection center. Plant disease fungi may be obligate parasites; that means they can live only on living plants. Those that can grow on dead organic matter as well as living plants are known as facultative saprophytes. Facultative parasites grow mosly on non-living matter but can attack plants. Examples of fungus diseases are Verticillium wilt, damping-off, powdery mildew, Texas root-rot, smuts and rusts.

Other forms of plant life, in addition to bacteria and fungi, may cause plant disease. Algae rarely cause disease, but in Asia, a green alga causes severe injury to tea and coffee. Parasitic seed-bearing plants such as dodder, broomrope and mistletoe cause economic damage to crop plants.

Viruses are pathogenic entities which attack many forms of life, including bacteria and plants. Virus particles, rod or spherical in shape, are so tiny that only an electron microscope makes them visible. Virus particles may enter plants by mechanical inoculations, insect feeding or vegetative propagation. Cigarette smokers are common carriers of tobacco mosaic virus and transmit it to tomato and related plants. Viruses also are carried in seed, tubers and bulbs. Viruses can cause leaf spotting, stunted growth and death of the plant. In some plants, however, viruses are present but fail to show symptoms. Examples of virus diseases are yellow dwarf of barley and cucurbit viruses (See individual disease section of this publication).

GROWTH AND REPRODUCTION OF PLANT PATHOGENS

The ideal characteristics of a successful plant pathogen are: 1) Virulence; the relative strength of a pathogen's ability to cause a destructive disease. 2) Rapid growth; it can multiply rapidly both as a saprophyte and parasite. 3) Wide host range; it can multiply on many kinds of wild and cultivated plants. 4) Dissemination; propagative bodies are produced abundantly and widely disseminated by wind, water, animals, insects and man.

General Requirements for Growth

Nutrient requirements for pathogenic bacteria and fungi are essentially the same as those of green plants. Since they do not possess chlorophyll, they cannot carry on photosynthesis and must get their food from living or non-living organisms or their products. That is, they must live as parasites or saprophytes. In addition, some require growth factors or vitamins, others can synthesize their needs.

1. Host Range. Obligate parasites can grow and produce only on living host. The rusts and powdery mildews, for example, have not been grown on non-living substrates. Most other plant pathogens can also grow on dead plants or plant parts and on artificial media. They are known as facultative saprophytes. The range of hosts for different pathogens varies widely; some are restricted to single species, others to a single family and others to a wide variety of plants. They differ in their ability to attack different tissues. Rhizoctonia may kill seedlings and rot roots, but cannot attack the woody cells of mature trees, while others can only attack the woody cells. Some pathogens affect

all parts of the host plant but produce different effects on each part.

Some pathogens require two taxonomically distinct kinds of hosts, either for persistance or for developing their complete life cycle. One stage develops on one host and the other stage on the second host. Some of these stages cannot infect the host on which they were produced.

2. Environmental Factors Affecting Growth. Many environmental factors affect the growth of pathogens. In some cases, pH may be a limiting factor in the growth of some pathogens. The pathogen that causes club-root of cabbage is inhibited in alkaline soils, while potato scab, caused by *Streptomyces scabies* is generally inhibited in acid soils.

Temperature is another environmental factor of importance to the growth of certain pathogens. The cardinal temperatures (minimum, optimum, and maximum) differ widely with the pathogen.

A third factor that affects pathogens is the biotic environment. The pathogen must compete with other organisms that are antibiotic to it. Thus, the hay bacillus, *Bacillus subtilus*, inhibits the growth of *Helminthosporium sativum*, the cause of root rot of cereals.

3. Reproduction of Bacteria and Fungi. Reproduction in bacteria is by simple fission. The conditions that favor their growth, also favor their reproduction. Fungi produce many special reproductive structures called spores on which their classification is based. Many reproduce both asexually (usually rapid) and sexually (survives unfavorable growing conditions). Generally, growth continues as long as nutritional and other factors are favorable. When checked, sporulation occurs. The incubation period varies considerably. The range of incubation periods will vary from 4-5 days in the case of the potato late blight fungus to almost a year for the fungus that causes loose smut of wheat.

THE DISSEMINATION OF PLANT PATHOGENS

The Requirements for Successful Dissemination

The requirements for a successful plant pathogen are rapid multiplication, efficient spore liberation, long-lived inoculum and abundant, timely and widespread dissemination. The principle agents of dissemination are wind, water, insects, animals other than insects, and man.

1. Principle Agents of Dissemination. Little is known about wind dissemination of bacteria or viruses. Wind, however, is very instrumental in the case of fungi. Spores have been caught 14,000 feet above infected fields and others have been caught over the Caribbean 600 miles from their nearest possible source. Some fungi are only disseminated locally by the wind, others such as *Puccinia graminis tritic* are spread over a large area by the wind. The repeating stage of this fungus survives the winter in Texas and in Mexico, but not the hot, dry summer. In the spring, mass air movements occur from south to north carrying the spores hundreds of miles in a few hours. In 1923, five successive waves carried the fungus 2,000 miles from Texas to the Canadian border in two months. In 1953 (early June) it was estimated

that 4,000 tons of spores, 150 billion to the pound, were produced on 4 million acres of wheat in northern Oklahoma and south-central Kansas. The winds carried the spores northward and deposited them at the rate of 3.5 million per acre over 40,000 square miles in the Dakotas and Minnesota. In the fall, the air masses move southward, carrying inoculum back to Texas and Mexico for overwintering. Bacteria and fungi spores extruded in gelatinous masses or spore-horns can be dispersed and washed away by water. Splashing and splattering rain water may distribute them to other parts of the same plants or to neighboring plants. Some pathogens have been observed to be disseminated by surface water.

Insects may be responsible for or aid in the direct production of disease without the aid of a pathogen, usually by the injection of a toxic substance in the tissues of the plant, e.g. hopperburn of potatoes. Insects may also disseminate pathogens through their feeding habits. They may inoculate the host with a pathogen. They may aid in the entry of the pathogen into the plant by providing openings in the host. Insects may preserve the pathogen by providing for its overwintering in the body of the insect or they may transfer the pathogen from a weed host to the crop plants. Some insects can transmit a virus to their progeny through eggs.

It is not known how important animals other than insects are for the dissemination of plant pathogens. Birds have been noted to be carrying fungus spores, but their effectiveness as carriers has not been established.

In transporting plant and plant products, man has also carried pests, pathogens and weed seeds. Plant pathogens may also be transmitted from field to field on farm implements. A pathogen may become far more destructive in an area where it is introduced than in the region of its origin, either because the new environmental conditions are most favorable or because the species or varieties of the new host plant are more susceptible. There are cases where pathogens, relatively harmless to native plants, have become extremely virulent when introduced to different varieties of the host plant.

INFECTION BY PLANT PATHOGEN

Sequence of Events for Growth

For a fungus disease to be produced, the following sequence of events must take place: 1) The spore must land on a susceptible surface of the host plant (inoculation). 2) The spore must germinate (germination). 3) The germ tube must grow and enter into the host tissue (penetration). 4) The hyphae must obtain nutrients for production on mycelium (establishment of fungus in the host).

The disease inoculum may consist of spores, vegetative mycelium, seeds (as in the case of dodder) or eggs (as in the case of nematodes). There is a great variation in the time required for germination; some germinate in 40 minutes while other may take 40 hours. Some spores can germinate immediately after liberation, others require a rest period. Moister is required for the germination of most spores and temperature requirements vary greatly.

Pathogens may enter plants in one or more of the following ways: through wounds, through natural openings, or directly through plant surfaces. Often pathogens do not discriminate as to what plants they penetrate. They may or may not grow after entrance; thus host reactions range from immunity to susceptibility. In the establishment of disease, the genetic nature of both the host and the pathogen must be considered. Is the host susceptible or resistant? Is the pathogen virulent or non-virulent? This host-parasite relationship is affected by environment. Thus temperature extremes may inhibit the establishment of a virulent pathogen in a susceptible host. Pathogens may be divided according to their means of establishment in the host; those that kill cells and disorganize tissue as the pathogen advances, (an example would be the bacterium Erwinia amylovera which causes fire blight) and those that obtain their nutrients from living cells, often without killing them (an example would be Erysiphe spp which causes powdery mildew).

PRINCIPLES OF PLANT DISEASE CONTROL

By control of a plant disease, we mean the reduction in the amount of injury it may cause. There are four main methods of plant disease control: exclusion, eradication, protection and use of resistant varieties.

Methods of Plant Disease Control

1. Exclusion refers to measures designed to keep pathogens from entering the area or sphere in which the host is growing or to reduce to a minimum the extent to which the pathogen is introduced. The sphere may include flats, greenhouses, gardens, fields, regions, countries, and continents. These measures include compulsory quarantines and inspection; embargoes; voluntary inspection and certification of planting stocks, together with their production in areas where the pathogen is minimized or excluded by unfavorable environment and inspection of perishable fruits and vegetables at shipping points. Exclusion will not control pathogens that produce wind blown spores that can easily cross barriers.

Major plant pests and plant diseases cause billions of dollars of damage each year in the United States alone. Over half of these pests and diseases were introduced from other countries. Plant quarantine refers to legal restrictions on the movement of commodities for the purpose of preventing or delaying the establishment of plant pests and diseases in areas where they are not known to occur. Great economic loss may be sustained by the introduction and establishment of pests and pathogens into areas where a biological balance between host and pathogen has not been reached. When the environment for the development of the introduced pathogen is especially favorable and the number of susceptible hosts is large, a severe epidemic may result. Thus, it is necessary to regulate the movement of plant materials that might be infested with pests or pathogens. Some important introductions of foreign pathogens into the United States are white-pine blister rust, chestnut blight, citrus canker, potato black wart, and Dutch Elm disease. Today over 150 countries or political units have established quarantines to control the movement of plant and animal materials from one geographic area to another. In addition, hundreds of domestic quarantines have been established. In the United States, the first

12856 J5828
12857 J5828

quarantine law was passed in Connecticut in 1726 to prevent the movement of the common barberry which was suspected of being responsible for stem rust epidemics. In 1881 the United States passed a domestic quarantine law to prevent the spread of the grape-gall louse. Finally, in 1912 the Federal Plant Quarantine Law was passed to prevent the importation of pests and diseases from abroad. An example of a quarantine in effect is the quarantine of citrus nursery stock which prohibits citrus plants from Europe, Asia, Africa, South America or Central America from entering the United States. Quarantine enforcement is difficult. Both laxness and excessive strictness is criticized. To be successful, quarantine regulations must be scientifically sound and administratively feasible. Thus, before a quarantine is established, a great deal of information is needed. The nature of the pathogen, the mode of dissemination, the mode of action, the host range and its natural barriers must all be taken into consideration. Quarantine regulations are classified as exclusive or regulatory. Regulatory conditions include inspection to see if plants are disease free, routine fumigation, and the holding of propagative stock under quarantine for a stated period of time. Exclusive quarantines prohibit the importation of plant materials. Exclusive quarantines are established when it is impossible to make certain that virulent pathogens are not accompanying plant materials.

2. Eradication consists of measures which are concerned with the elimination of the pathogen after it has become established in the sphere where the host is growing. These measures include: (a) eradication of alternate host such as currents in white pine blister rust or cedars in cedar-apple rust; (b) eradication of wild or overwintering host such as certain weed host of plant viruses (this practice often is too expensive and eradication of the insect vector that spreads the virus is more feasible); (c) eradication of overwintering debris as sources of primary inoculum by crop rotation such as in cotton-angular leaf spot (the organism that causes this disease must live on cotton residue); (d) sterilization, and/or sanitation as in the case of soil sterilization for nematodes or washing of fruit at the packing shed before shipping; (e) eradication of the pathogen from propagative parts of the host such as seeds, tubers, and bulbs as in the case of hot water treatment of barley seed for loose smut; (f) eradication from growing parts of the host by surgery as the removal of cankers from pear and apple trees with fire blight; (g) eradication of host and pathogen as in the removal and destruction of citrus trees with citrus canker; (h) eradication of established pathogens by means of a chemical as in the case of fungicide application for powdery mildew.

3. Protection refers to measures in which it is assumed that the host will be exposed to the pathogen and that infection will occur unless protection procedures are undertaken. Measures taken to regulate environment include; 1) selection of growing areas, as in the case of growing certified seed potatoes in northern states where there are "disease-proof" areas or the growing of bean and crucifer seed in the west, 2) protection by regulation of storage and transportation environment as in cooling, moisture control and air movement control for fruits and vegetables on their way to the consumer and 3) regulation of greenhouse environment as to humidity and temperature.

Cultural practices followed to protect hosts include; 1) time of planting, as in planting cotton when the soil temperature will prohibit damping-off of seedlings; 2) regulation of soil moisture; 3) adjustment of soil pH as is the case of lowering the pH to protect against potato scab and 4) regulation of fertility level and balance as in limiting nitrogen fertilizer on pear trees as protection against fire blight or addition of chelated iron to prevent cholorosis.

Proper handling practices assist in the prevention of bruises caused by handling fruit and vegetables.

Chemicals are used to protect plant parts before the pathogen invades the plant, as in the application of a fungicide to protect against late blight of potatoes and tomatoes. Another example of the use of chemicals for host protection is pre-plant seed treatment to control pre-emergence damping-off.

Tubers, bulbs and other propogative plant parts are treated with an antibiotic dip to protect from crowngall. Bare root stock may also be treated in this way.

Row fumigation is used to treat soil for protection against nematodes.

4. Resistant varieties are used to control many of the serious plant diseases which cannot be controlled by seed treatment, chemical sprays or cultural methods. In these cases, the use of resistant varieties is the cheapest way to control diseases. In breeding for disease resistance the plant breeder is dealing with two series of heritable variations; (1) those of the host plant and (2) those of the pathogen.

The plant breeder tests the progenies by exposing them to the species of bio-types of the pathogen with which he is working. Environmental conditions ideally suited for the best development of the disease are maintained. Plants which are resistant to the pathogen are selected from the hybrids and later generations with close attention to other desirable characteristics such as yield. Having obtained suitable parental materials, the breeder attempts to combine disease resistance from one plant with the desirable commercial or cultural characteristics of the other.

Examples of diseases that can be controlled through the use of resistant varieties include flax wilt, cabbage yellows and stem and crown rusts of oats. An example of a way resistant varieties were developed, it was noted that when flax was grown on the same land for several years, serious losses from wilt often resulted. Hirotsuka in Japan (1896) and Bolley in North Dakota (1901) found that a Fusarium was responsible. Previously Bolley had noticed that a few plants survived each year in his "disease garden." He selected these, sowing the seed in the same plot and by repeated selection obtained wilt resistant varieties.

5. Kinds of disease resistance. There are two kinds of disease resistance: 1) Resistance to entrance; the epidermis of some plants is so resistant that the germ tube cannot penetrate; 2) Resistance after

entrance; the germ tube quickly kills a few host cells and in turn is killed by substances from the host cell.

In addition to the above, plant diseases may be avoided or minimized by: 1) Escape; where rapid growth and early maturity enables plants to escape attack of plant pathogens; 2) Disease tolerance; in disease tolerance the plant can live with the pathogens or else overcome their adverse effects by compensating growth. An example would be where new roots are sent out quickly when some have been killed by root rot organisms.

SUMMARY

Man depends upon plants for food, shelter and clothing. The cost of these items has increased millions of dollars each year because plant diseases render unfit for consumption or reduce the yield of much of the farmer's production. Additional millions of dollars are spent in attempts to control or learning how to control plant diseases.

Plant disease may be classified as to symptoms or causal agents. Symptoms or signs are manifest as superficial, tissue death, underdevelopment, abnormal overgrowth or wilt. Agents which cause disease are classified as inanimate or animate. The inanimate causal agents may be unfavorable soil conditions or weather, improper cultural practices, industrial contaminants or the results of uncontrolled plant metabolism. Animate causal agents consist of higher animals, insects, nematodes, baceteria, fungi, algae, parasitic seed plants and viruses.

Plant pathogens may obtain their food from either dead or living matter and may be selective or have a wide range of hosts. Environment influences their growth and reproduction. Plant pathogens are spread by wind, water, insects, animals and man. Normally, for a plant to become infected by a pathogen, it must be inoculated. The pathogen must germinate and penetrate the host to become established. Plant diseases are controlled by excluding the pathogen from the host, eradicating the pathogen from the host, protecting the host from the pathogen or by using varieties resistant to the pathogen. Further research is needed to learn new and more effective ways of controlling plant diseases.

PRINCIPLES OF PLANT PATHOLOGY

IN

EXERCISES AND EXPERIMENTS

The exercises included in this section are designed to be performed by individual students or students working in teams. Most of the exercises require a period of time before the final results can be recorded. It is desirable that the experiments be carefully planned ahead of time in order that results will be available at the appropriate time that the material or principle it demonstrates is being discussed.

Listed below are seven vital functions in the life of plants involving food production and growth.

1. Food stored in seed, roots or modified stems maintain respiration of a bud or embryo and supports growth after dormancy.

2. The stored foods are hydrolized into simple sugars and amino acids and transferred to the expanding bud or embryo in the spring.

3. The new plant sends out roots with limited food reserves. Roots acquire water and nutrients from the soil.

4. Food reserves from seed and solutes from the soil are used to inaugurate meristimatic activity in the young plant. Food source is transferred from seed to the new leaves.

5. As the seedling enlarges water must be transferred from the roots to the leaves to sustain photosynthesis.

6. In the leaves carbon dioxide and water are combined to form sugars.

7. Foods are transferred from leaves to meristems and storage organs where they promote growth, are used in reproduction, or are stored.

The exercises included in this section are designed to demonstrate types of parasitism which interfere with the vital functions listed above. The purpose or function interfered with is listed below followed by the number or numbers denoting the exercises which are designed to demonstrate how this happens. There is more than one exercise for several of the functions. The instructor may wish to use all of the exercises or select a lesser number.

1. Introductory. Exercises 1, 2

2. Destruction of stored foods or storage organs. Soft rots and seedling decay. Exercises 3, 4, 5

3. Destruction of seedlings, damping-off diseases. Exercise 5

4. Diseases resulting from interference with uptake of water and solutes from the soil. Root rot diseases. Exercise 6

BUREAU OF NAVAL PERSONNEL

NAVY TRAINING COURSE NAVPERS 16193-A

PREFACE

Fluid Power is written primarily to provide coverage of the hydraulic and pneumatic knowledge factors required of men of the U. S. Navy and Naval Reserve who desire to advance in certain ratings. The subject matter covers a broad area of Qualifications for Advancement in Rating, all of which are common to several rates and ratings.

Combined with the necessary practical experience, this training course will assist nonrated men in preparing for advancement to Petty Officer Third Class in the specific ratings requiring a knowledge of fluid power. This training course should also be valuable as a review and reference source for personnel of more senior rates.

This training course was prepared by the U. S. Navy Training Publications Center, Memphis, Tennessee, for the Bureau of Naval Personnel.

THE UNITED STATES NAVY

GUARDIAN OF OUR COUNTRY

The United States Navy is responsible for maintaining control of the sea and is a ready force on watch at home and overseas, capable of strong action to preserve the peace or of instant offensive action to win in war.

It is upon the maintenance of this control that our country's glorious future depends; the United States Navy exists to make it so.

WE SERVE WITH HONOR

Tradition, valor, and victory are the Navy's heritage from the past. To these may be added dedication, discipline, and vigilance as the watchwords of the present and the future.

At home or on distant stations we serve with pride, confident in the respect of our country, our shipmates, and our families.

Our responsibilities sober us; our adversities strengthen us.

Service to God and Country is our special privilege. We serve with honor.

THE FUTURE OF THE NAVY

The Navy will always employ new weapons, new techniques, and greater power to protect and defend the United States on the sea, under the sea, and in the air.

Now and in the future, control of the sea gives the United States her greatest advantage for the maintenance of peace and for victory in war.

Mobility, surprise, dispersal, and offensive power are the keynotes of the new Navy. The roots of the Navy lie in a strong belief in the future, in continued dedication to our tasks, and in reflection on our heritage from the past.

Never have our opportunities and our responsibilities been greater.

CHAPTER 1

INTRODUCTION

Fluid Power, NavPers 16193-A, presents in logical sequence many of the fundamental concepts in the fields of hydraulics and pneumatics. Emphasis is placed primarily on the theory of operation of typical fluid power components and systems that have applications in naval equipment.

This training course is intended as a basic reference for all personnel of the Navy whose duties require them to have a knowledge of the fundamentals of fluid power. Individual rating courses should be consulted for information concerning the application of fluid power to specific equipments.

A brief summary of the contents of this training course is given in the following paragraphs:

Chapter 2 describes the physical properties and characteristics of fluids, both at rest and in motion. This description includes the similarities and differences of liquids and gases.

Chapter 3 discusses the qualities of satisfactory fluids for fluid power systems and the types of fluid used. Included is a section on liquid contamination concerning the types and effects of contaminants and control of the contamination problem. Also included are some of the potential hazards involved with the handling of compressed gases.

Chapter 4 gives brief descriptions of the components which are contained in basic and simple fluid power systems, including examples of simple systems in common applications. This chapter also includes the types of diagrams and the different symbols used in the illustration of fluid power systems.

Chapter 5 deals with the lines—pipes, tubing, and flexible hose—used to convey fluid under pressure, and the various connectors employed to join the components of fluid power systems.

Chapter 6 describes the functions and types of reservoirs, strainers, filters, and accumulators, and their application in fluid power systems.

The power supply for fluid power systems is covered in chapter 7. This includes the classifications, types, and operation of the pumps used in hydraulic systems and the compressors used in pneumatic systems.

Chapter 8 discusses the purposes and types of seals and packings used in fluid power systems, including the different materials used in their construction.

Chapter 9 describes the operation of the different valves used to control the flow of fluid and the meters used to measure the quantity and rate of flow.

Chapter 10 covers the types and operation of gages used for measuring fluid pressure and the valves used for the control of fluid pressure.

The types and operation of directional control valves are described in chapter 11.

Chapter 12 deals with the actuators used in fluid power systems. This includes the operation of actuating cylinders, motors, and turbines which are used to convert fluid power to mechanical force and motion.

Chapter 13 briefly describes various systems which illustrate some of the applications of fluid power in the Navy.

A glossary of terms commonly used in the field of fluid power is provided in appendix I. Reference to the glossary is directed at various places throughout the course whenever immediate reference to the glossary will serve to clarify the text. Appendix II provides a film list of selected films which may be used in conjunction with this course to clarify or expand coverage of certain areas in the field of fluid power.

12893

The remainder of chapter 1 is devoted to the introduction to fluid power, including brief sections on the history, development, and applications of hydraulics and pneumatics, and concludes with a discussion on the advantages and problems of fluid power applications.

FLUID POWER

The term fluid power has recently been established to include the generation, control, and application of smooth, effective power of pumped or compressed fluids (either liquids or gases) when this power is used to provide force and motion to mechanisms. This force and motion may be in the form of pushing, pulling, rotating, regulating, or driving. Fluid power includes hydraulics, which involves liquids, and pneumatics, which involves gases. Liquids and gases are similar in many respects and therefore are described as fluids in most sections of this course. The differences are pointed out in the appropriate areas. In these areas they are described separately as liquids and gases, or, as in the following sections, as hydraulics and pneumatics.

HYDRAULICS

The word hydraulics is a derivative of the Greek word hydro (meaning water) and aulis (meaning tube or pipe). Originally, the study of hydraulics covered the physical behavior of water at rest and in motion. Use has broadened its meaning to include the physical behavior of all liquids, including the media used in present day hydraulic systems.

The science includes, for example, the manner in which liquids act in tanks and pipes, dealing with their properties and with ways of utilizing these properties. It includes the laws of floating bodies and the behavior of liquids on the submerged surfaces of dams and sluice gates. It treats the flow of liquids under various conditions, and ways of directing this flow to useful ends, as well as many other related subjects.

Development

Although the modern development of hydraulics is of comparatively recent date, the ancients were familiar with many hydraulic principles and their applications. The Egyptians and the ancient peoples of Persia, India, and China conveyed water along channels for irrigation and domestic purposes, using dams and sluice gates to control the flow. The ancient Cretans had an elaborate plumbing system. Archimedes studied the laws of floating and submerged bodies. The Romans constructed aqueducts to carry water to their cities.

After the breakup of the ancient world, there were few new developments for many centuries. Then, over a comparatively short period, beginning not more than three or four hundred years ago, the physical sciences began to flourish, thanks to the discovery of principles basic to all of them, and to the invention of many new mechanical devices. Thus, the fundamental law underlying the entire science of hydraulics was discovered by Pascal in the 17th century.

Pascal's theorem was as follows: "If a vessel full of water, and closed on all sides, has two openings, the one a hundred times as large as the other, and if each is supplied with a piston that 'fits it exactly', then a man pushing the small piston will exert a force that will equilibrate that of one hundred men pushing the large piston and will overcome that of ninety-nine men." (This is the basic principle of hydraulics and is covered in detail in chapter 2.)

For Pascal's law to be made effective for practical applications, it was necessary to have a piston that "fit exactly." It was not until the latter part of the 18th century that methods were found to make these snugly fitted parts required in hydraulic systems. This was accomplished by the invention of machines which were used to cut and shape the necessary closely fitted parts and, particularly, by the development of seals and packings. Since this time, such components as valves, pumps, and motors have been developed and refined to make hydraulics one of the leading methods of transmitting power.

Application

As previously stated, the control of flow of water for irrigation and domestic use depends upon the application of hydraulic principles. Today, however, the term hydraulic commonly refers to power hydraulics in which liquid is used under controlled pressure to do work. This course deals primarily with this phase of hydraulics.

Today, hydraulic power is used to operate many different tools and mechanisms. In a

12894

garage, a mechanic raises the end of an automobile with a hydraulic jack. Dentists and barbers use hydraulic power to lift their chairs to a convenient working height by a few strokes of a lever. Hydraulic doorstops keep heavy doors from slamming. Hydraulic brakes have been standard equipment on automobiles for approximately 30 years. Most automobiles are equipped with automatic transmissions which are hydraulically operated. Power steering is another application of hydraulic power. Construction men depend upon hydraulic power for the operation of various components of their equipment. For example, the blade of a bulldozer is operated by fluid power.

During the period preceding World War II, the Navy began to apply hydraulics to naval mechanisms extensively. Since then, naval applications have increased to the point where many ingenious hydraulic devices are used in the solution of problems of gunnery, aeronautics, and navigation. Aboard ship, hydraulic power is utilized to operate such equipment as anchor windlasses, power cranes, steering gear, remote control devices, power drives for elevating and training guns and rocket launchers, and elevators on aircraft carriers to transfer aircraft from the hangar deck to the flight deck and vice versa.

Most naval aircraft contain a network of hydraulic lines and components. Hydraulic power is used to operate such units as wheel brakes, landing flaps, antennas, speed brakes, control surfaces, and the retraction and extension of the landing gear. Many types of guided missiles contain hydraulic systems for the operation of flight control devices.

PNEUMATICS

Pneumatics is that branch of physics that deals with properties such as pressure, density, etc., of air and other gases. Pneumatics is a derivative of the Greek word pneuma, which means air, wind, or breath.

Development

There is no record of man's first use of air to do work. Probably the first were fans used to separate the chaff from grain and sails used to move ships. One of the first pneumatic devices was the blow gun used by primitive man. In the latter part of the 18th century, heated air was used to carry the first balloon aloft. The heated air was allowed to expand in the balloon, and therefore it became lighter than the surrounding air and caused the balloon to rise.

Every age of man has witnessed the development of devices to utilize air to do work. However, it can be seen that man used air for work long before he understood it.

Many of the principles of hydraulics apply to pneumatics. For example, Pascal's law applies to gases as well as liquids. Also, like hydraulics, the development of pneumatics depended upon closely fitted parts and the development of seals and packings. Since the invention of the air compressor, pneumatics has become a very reliable source for the transmission of power.

Application

In this course, pneumatics is considered as power transmitted and controlled through the use of compressed gas, usually air or nitrogen. Probably one of the greatest uses of pneumatic power is in the operation of the various types of pneumatic tools. Pneumatic drills, screwdrivers, and nut setters are operated by air motors. Riveting guns and chipping hammers are usually operated by air pressure. Compression tools such as rivet squeezers and punches are operated by pneumatic power. Trains, buses, and large trucks are normally equipped with air brakes.

Most models of aircraft contain pneumatic systems as an emergency means of operating those units which are normally operated hydraulically. Guided missiles utilize compressed gas as a power source for electric generators and hydraulic pumps. In some missiles, pneumatic power is utilized to operate flight control devices.

Pneumatics and hydraulics are combined for some applications. The lift used in garages and service stations is one example. Air pressure is applied to the surface of hydraulic fluid in a reservoir. The air pressure forces the hydraulic fluid to raise the lift. The accumulator, described in chapter 6, is another example of this combination.

ADVANTAGES OF FLUID POWER

The common use of fluid power is due to the fact that properly constructed fluid power systems possess a number of favorable characteristics. They eliminate the need for complicated

12895

systems of gears, cams, and levers. Motion can be transmitted without the slack inherent in the use of all solid machine parts. The fluids used are not subject to breakage as are mechanical parts, and the mechanism is not subject to great wear.

The different parts of a fluid power system can be conveniently located at widely separated points, and the forces generated are rapidly transmitted over considerable distances with small loss. These forces can be conveyed up and down or around corners with small losses in efficiency and no complicated mechanisms. Very large forces can be controlled by much smaller ones, and can be transmitted through comparatively small lines and orifices.

If the system is well adapted to the work it is required to perform, and if it is not misused, it can provide smooth, flexible, uniform action without vibration, and unaffected by variation of load. In case of overload, an automatic release of pressure can be guaranteed, so that the system is protected against breakdown or strain. Fluid power systems can provide widely variable motions in both rotary and straight-line transmission of power. Need for control by hand can be minimized. Finally, fluid power systems are economical to operate.

SPECIAL PROBLEMS

The extreme flexibility of fluid power elements gives rise to a number of problems. Since fluids have no shape of their own, they must be positively confined throughout the entire system. Special consideration must be given to the structural organization and the relation of parts of a fluid power system. Strong pipes and containers must be provided. Leaks must be prevented. This problem is acute with the high pressure obtained in many fluid power installations.

The pressures required in fluid power systems must be controlled and likewise the movement of the component fluids. This movement causes friction, within the fluid itself and against the containing surfaces, which if excessive, can lead to serious losses in efficiency. Foreign matter must not be allowed to accumulate in the system, where it will clog small passages or score closely fitted parts. Chemical action may cause corrosion. Above all, it is necessary to know how a fluid power system works, both in terms of the general principles common to all physical mechanisms and the peculiarities of the particular arrangement at hand.

Although solids differ in certain ways from liquids and gases, and although each substance—lead, tin, water, oil, nitrogen, etc.—has its own special properties, all kinds of matter show the same fundamental pattern of action and reaction. When the principles common to all physical science became clarified in early modern times, new possibilities of understanding and action were opened up for mankind. Thus, today when a person thoroughly grasps these principles, he is in a position to enlarge his power to understand and control the natural world.

Although solids are rigid and fluids are not, the knowledge of levers can be applied to fluid power situations. Just as a child weighing say 50 pounds can balance one weighing 100 pounds by sitting twice as far away from the balancing point, so in fluid power a force of 50 pounds applied over a certain area can balance a force of 100 pounds acting over twice that area.

The inventor or engineer who wants to move something is therefore always faced with a number of possibilities. The object to be moved could be pushed with a stick or pulled with a chain. A jet of water or a stream of air might be directed against it, or something could be thrown against it. If a weight is to be lifted, levers, gears, ropes and pulleys, chain hoists, screw jacks, hydraulic jacks, or the force of floatation might be used. Part of the system could make use of electricity, heat, or even light, as in the case of doors that open automatically when people approach.

Each method of accomplishing mechanical movements has its good points and its bad, its special capabilities, and its limitations. Ropes and chains, for example, can pull but they cannot push; fluid power elements can push but they cannot pull; solid rods can both push and pull but cannot go around corners like chains, ropes, or fluid power elements. Gears can operate continuously in a rotary motion, whereas a lever usually operates so that the arms of the lever move back and forth. And so it goes for every machine element. Though each obeys the same general physical laws, each also possesses special properties that must be taken into account.

CHAPTER 2

PHYSICS OF FLUIDS

Physics is the term applied to that area of knowledge in which the attempt is made to understand the basic and fundamental nature of matter and energy. It does not attempt to determine why matter and energy behave as they do in their relation to physical phenomena, but rather how they behave.

The personnel who operate fluid power systems should have a knowledge of the physics of fluids. The personnel who service and maintain fluid power systems must have a thorough understanding of the properties of fluids and the behavior of fluids under different circumstances.

STATES OF MATTER

Matter is any substance that occupies space and has weight. There are three states of matter—solids, liquids, and gases. Solids have a definite volume and a definite shape; liquids have a definite volume, but they take the shape of the containing vessel; gases have neither a definite volume nor a definite shape. Gases not only take the shape of the containing vessel, but they expand and fill the vessel, no matter what its volume.

Matter can change from one state to another. Water is a good example. At high temperature it has the gaseous state known as steam. At moderate temperatures it is a liquid, and at low temperatures it becomes ice, which is definitely a solid state. In this example, the temperature is the dominant factor in determining the state that the substance assumes. Pressure is another important factor that will effect changes in the state of matter. At pressures lower than atmosperic, water will boil and thus change into steam at temperatures lower than 212° Fahrenheit (F). Pressure is a critical factor in changing some gases to liquids or solids. Normally, when pressure and chilling are both applied to a gas, it assumes a liquid state. Liquid air, which is a mixture of oxygen and nitrogen, is produced in this manner.

FLUIDS

Both liquids and gases flow freely; for that reason both are called fluids, from the Latin word "fluidus" meaning to flow. A fluid is defined as a substance which changes its shape easily and takes the shape of its container. This applies to both liquids and gases. The characteristics of liquids and gases may be grouped under similarities and differences.

Similar characteristics are listed as follows:

1. Each has no definite shape but conforms to the shape of the container.
2. Both readily transmit pressures.

Differential characteristics are listed as follows:

1. Gases fill their containers completely, while liquids may not.
2. Gases are lighter than equal volumes of liquids.
3. Gases are highly compressible, while liquids are only slightly so.

These differences are described in the appropriate areas of the following discussion concerning the properties and characteristics of fluids at rest. Also included are some of the outside factors which affect fluids in different situations.

DENSITY AND SPECIFIC GRAVITY

The density of a substance is its weight per unit volume. The unit volume selected for use in the English system of measurement is 1 cubic foot. In the metric system it is 1 cubic centimeter. Therefore, density is expressed in pounds per cubic foot or in grams per cubic centimeter.

12897

5. Disease resulting from abnormal growth. Crown Galls. Club Root. Exercise 7

1. How to Use the Microscope

The microscope will be used frequently in studying the details of host cells and the structures of the pathogen which are not large enough to be seen clearly with the unaided eye. The microscope and the mount may be ruined if precautions are not observed. The following procedure will minimize this hazard and assist in quickly bringing the object into focus.

A. The microscope should be placed near the chest so the eye is brought directly over the ocular. The microscope should not be tilted; if it is tilted the liquid on the slides will flow off and it will also be difficult to obtain adequate light.

B. The correct amount of light may be attained by adjusting the substage mirror in the direction of the light source, so that a large amount of light will be reflected through the slide or mount to the ocular. An adjustable diaphragm beneath the microscope stage controls the amount of light. Various amounts of light will be required by different mounts. Adjust the amount of light until the greatest detail is obtained.

C. Use the following technique when focusing the microscope:

1. Turn the coarse adjustment to raise the tube, then place the slide on the stage.

2. Place the slide directly over the opening in the stage and hold the slide with the spring clamps on either side.

3. Lower the tube until the low power objective is within 1/8 inch of the slide or mount.
   DO NOT focus downward while looking through the microscope.

4. Slowly raise the tube with the coarse adjustment while watching through the microscope. Use the fine adjustment when the object is nearly in focus.

5. Move the slide to center the desired part in the field.

6. When higher magnification is needed, rotate the nosepiece until the highpower objective moves in place under the tube. This should be done gently. Never force the objective into position.

7. Move the fine adjustment up or down gently to bring the object into clear focus. Under highpower magnifications only certain areas of the field will be in focus at the same time. Small adjustments in focus will be necessary as various parts of the field are studied.

To find the density of a substance, its weight and volume must be known. Its weight is then divided by its volume to find the weight per unit volume.

EXAMPLE: The liquid which fills a certain container weighs 1497.6 pounds. The container is 4 feet long, 3 feet wide, and 2 feet deep. Its volume is 24 cubic feet (4 ft x 3 ft x 2 ft). If 24 cubic feet of liquid weighs 1497.6 pounds, then 1 cubic foot weighs $\frac{1497.6}{24}$ or 62.4 pounds. Therefore, the density of the liquid is 62.4 pounds per cubic foot.

This is the density of water at 4° centigrade (C) and is usually used as the standard for comparing densities of other substances. (In the metric system the density of water is 1 gram per cubic centimeter.) The standard temperature of 4° C is used when measuring the density of liquids and solids. Changes in temperature will not change the weight of a substance, but will change the volume of the substance by expansion or contraction thus changing its weight per unit volume.

The procedure for finding density applies to all substances; however, it is necessary to take pressure into consideration when finding the density of gases. Temperature is more critical when measuring the density of gases than it is for other substances. The density of a gas increases in direct proportion to the pressure exerted on it. Standard conditions for the measurement of the densities of gases have been established at 0° C for temperature and 76 centimeters of mercury. (This is the average pressure of the atmosphere at sea level.) Density is computed on these conditions for all gases.

It is often necessary to compare the density of one substance with that of another. For this purpose a standard is needed. Water is the standard that physicists have chosen with which to compare the densities of all liquids and solids. For gases, air is most commonly used. Hydrogen is sometimes used as a standard for gases. In physics, the word specific implies a ratio. Thus, the ratio of the weight of a unit volume of some standard substance, measured under the standard pressure and temperature conditions, is called specific gravity. The terms specific weight or specific density are sometimes used to express this ratio.

The following formulas are used to find the specific gravity (sp gr) of liquids and solids.

$$\text{sp gr} = \frac{\text{Weight of the substance}}{\text{Weight of an equal volume of water}}$$

or,

$$\text{sp gr} = \frac{\text{Density of the substance}}{\text{Density of water}}$$

The same formulas are used to find the density of gases by substituting air or hydrogen for water.

Specific gravity is not expressed in units, but as pure numbers. For example, if a certain hydraulic liquid has a specific gravity of 0.8, 1 cubic foot of the liquid weighs 0.8 times as much as a cubic foot of water—62.4 times 0.8 or 49.92 pounds. In the metric system, 1 cubic centimeter of a substance with a specific gravity of 0.8 weighs 1 times 0.8 or 0.8 gram. (Note that in the metric system the specific gravity of a liquid or solid has the same numerical value as its density. Since air weighs 1.293 grams per liter, the specific gravity of gases does not equal the metric densities.)

Specific gravity and density are independent of the size of the sample under consideration and depend only upon the substance of which it is made. See table 2-1 for typical values of specific gravity for various substances.

A device called a hydrometer is used for measuring specific gravity of liquids. This device consists of a tubular shaped glass float which is contained within a larger glass tube. (See fig. 2-1.) The larger glass tube provides the container for the liquid. A rubber suction bulb draws the liquid up into the container. There must be enough liquid to raise the float and prevent it from touching the bottom. The float is weighted and has a vertically graduated scale. To determine specific gravity the scale is read at the surface of the liquid in which the float is immersed. An indication of 1000 is read when immersed in pure water. When immersed in a liquid of greater density the float rises, indicating a greater specific gravity. For liquids of lesser density the float sinks, indicating a lower specific gravity.

An example of the use of the hydrometer is when used to determine the specific gravity of the electrolyte (battery liquid) in an automobile battery. When a battery is discharged, the calibrated float immersed in the electrolyte will indicate 1150. The indication of a fully charged battery is 1270.

BUOYANCY

A body submerged in a liquid or a gas weighs less than when weighed in free space.

12898

Table 2-1.—Typical values of specific gravity

Solids	sp gr	Liquids (Room temperatures)	sp gr	Gases (Air standard at 0°C and 76.0 centimeters of mercury)	sp gr
Aluminum	2.7	Alcohol, ethyl	0.789	Air	1.000
Bronze	8.8	Gasoline	0.68-0.72	Hydrogen	0.0695
Copper	8.9	Oil (paraffin)	0.8	Nitrogen	0.967
Ice	0.917	Water	1.00	Oxygen	1.105

This is due to the upward force that the fluid exerts on the submerged body. An object will float if this upward force of the fluid is greater than the weight of the object. Objects denser than the fluid, even though they sink readily, appear to lose a part of their weight when submerged. An individual can lift a larger weight under water than he can possibly lift in the air. The upward force which any fluid exerts upon a body placed in it is called buoyant force.

The following experiment is illustrated in figure 2-2. The overflow can is filled up to the spout with water. The heavy metal cylinder is first weighed in still air and then is weighed while completely submerged in the water. The difference between the two weights is the buoyant force of the water. As the cylinder is lowered into the overflow can, the water is caught in the catch bucket. The volume of water which overflows equals the volume of the cylinder. (The volume of irregular shaped objects may be measured by this method.) If this experiment is performed carefully, the weight of the water displaced by the metal cylinder exactly equals the buoyant force of the water.

Experiments similar to this were performed by Archimedes (287-212 B.C.) As a result of his experiments he discovered that the buoyant force which a fluid exerts upon a submerged body is equal to the weight of the fluid the body displaces. This statement is referred to as Archimedes' principle. This principle applies to all fluids, gases as well as liquids. Just as water exerts a buoyant force on submerged objects, air exerts a buoyant force on objects submerged in it.

TEMPERATURE

As indicated in the following paragraphs, temperature is a dominant factor affecting the physical properties of fluids. It is of particular concern when calculating changes in the state of gases.

The three temperature scales used extensively are the centigrade, the Fahrenheit, and the absolute or Kelvin scales. The centigrade scale is constructed by using the freezing and boiling points of water, under standard conditions, as fixed points of zero and 100, respectively, with 100 equal divisions between. The Fahrenheit scale uses 32° as the freezing point of water and 212° as the boiling point, and has 180 equal divisions between. The absolute or Kelvin scale is constructed with its zero point established as 273° C, or 459.4° F below the freezing point of water. The relations of the other fixed points of the scale are shown in figure 2-3.

Absolute zero, one of the fundamental constants of physics, is commonly used in the study of gases. It is usually expressed in terms of the centigrade scale. If the heat energy of a given gas sample could be progressively reduced, some temperature should be reached at which the motions of the molecules would cease entirely. If accurately determined, this temperature could then be taken as a natural reference, or as a true "absolute zero" value.

Experiments with hydrogen indicated that if a gas were cooled to -273.16° C (used as -273 for most calculations), all molecular motion would cease and no additional heat could be extracted from the substance.

12899

Figure 2-1.—A hydrometer.

Figure 2-2.—Measurement of buoyant force.

When temperatures are measured with respect to the absolute zero reference, they are expressed as zero in the absolute or Kelvin scale. Thus, absolute zero may be expressed as 0° K, as -273° C, or as -459.4° F (used as -460 for most calculations).

Personnel working with temperatures must always make sure which system of measurement is being used and how to convert from one to another. The conversion formulas are shown in figures 2-3. For purposes of calculations, the Rankine scale illustrated in figure 2-4 is commonly used to convert Fahrenheit to absolute. For Fahrenheit readings above zero, 460° is added. Thus, 72° F equals 460° plus 72° or 532° absolute. If the Fahrenheit reading is below zero, it is subtracted from 460°. Thus -40° F equals 460° minus 40° or 420° absolute. It should be stressed that the Rankine scale does not indicate absolute temperature readings in accordance with the Kelvin scale but these conversions may be used for the calculations of changes in the state of gases.

The Kelvin and centigrade scales are used more extensively in scientific work and, therefore, some technical manuals may use these scales in giving directions and operating instructions. The Fahrenheit scale is commonly used in the United States and most people are

12900

Figure 2-3.—Comparison of Fahrenheit, centigrade, and Kelvin temperature.

familiar with it. Therefore, the Fahrenheit scale is used in most areas of this course.

PRESSURE

The term pressure as used throughout this course, is defined as a force per unit area. It is further defined in relation to other factors later in this chapter. Pressure is usually measured in pounds per square inch (psi). Sometimes pressure is measured in inches of mercury, or for very low pressure, inches of water.

Pressure may be in one direction, several directions, or in all directions. (See fig. 2-5.) The ice (a solid) exerts pressure downward only. Water (a fluid) exerts pressure on all surfaces with which it comes in contact. Gas (a fluid) exerts pressure in all directions. Gas exerts pressure on all sides because it completely fills the container.

Atmospheric Pressure

The atmosphere is the whole mass of air surrounding the earth. While it extends upward for about 500 miles, the section which is of primary interest is that portion of the air which rests on the earth's surface and extends upward for about 7 1/2 miles. This layer is called the troposphere and the higher above the earth the lower the pressure. This is because air has weight. If a column of air 1-inch square extending all the way to the "top" of the atmosphere could be weighed, this column of air would weigh approximately 14.7 pounds at sea level. Thus, atmospheric pressure at sea level is approximately 14.7 pounds per square inch

Figure 2-4.—Fahrenheit and absolute temperature compared (Rankine scale).

Figure 2-5.—Exertion of pressure.

(psi). (See fig. 2-6.) As one ascends, the atmospheric pressure decreases approximately 1.0 psi for every 2,343 feet. However, below sea level, in excavations and depressions, atmospheric pressure increases. Pressures under water differ from those under air only because the weight of the water must be added to the pressure of the air.

Atmospheric pressure can be measured by any of several methods. The common laboratory method employs the mercury column barometer. A mercury column consists of a glass tube

Figure 2-6.—Atmospheric pressure.

approximately 34 inches in length, sealed at one end, then completely filled with mercury, and inverted in an open cup partially filled with mercury. (See fig. 2-7.)

The mercury in the tube settles down, leaving an evacuated space in the upper end of the tube. The height of the mercury column serves as an indicator of atmospheric pressure. At sea level and at a temperature of 0° C, the height of the mercury column is 76 cm or approximately 30 inches, which represents a pressure of 14.7 psi. The 30-inch column is used as a reference standard.

At higher levels, the atmospheric pressure on the surface of the mercury in the open cup is less than at sea level; hence, the column of mercury in the tube settles lower. These variations in the height of the mercury column represent changes in atmospheric pressure which may be calibrated in terms of altitude with reference to sea level.

Another device used to measure atmospheric pressure is the aneroid barometer. (See fig. 2-8.) This barometer consists of a small sealed metal drum that has been partially evacuated and which has one side or end made of corrugated metal. This thin metal moves in or out with the variation of pressure on its external surface. This movement is transmitted through a system of levers to a pointer. The pointer is pivoted so that it sweeps across a graduated scale calibrated either in psi or in feet to designate an altitude corresponding to the indicated pressure.

The atmospheric pressure does not vary uniformly with altitude. It changes more rapidly at lower altitudes because of the compressibility of the air which causes the air layers close

12902

Figure 2-7.—Measurement of atmospheric pressure—mercury barometer.

Figure 2-8.—Aneroid barometer.

to the earth's surface to be compressed by the air masses above them. This effect, however, is partially counteracted by contraction of the upper layers due to cooling. The cooling tends to increase the density of the air.

Atmospheric pressures are quite large, but in most instances practically the same pressure is present on all sides of objects so that no single surface is subjected to a great load.

Absolute Pressure

As stated previously, absolute temperature is used in the calculation of changes in the state of gas. It is also necessary to use absolute pressure for these calculations.

Absolute pressure is measured from absolute zero pressure rather than from normal or atmospheric pressure (approximately 14.7 psi). Gage pressure is used on all ordinary gages, and indicates pressure in excess of atmospheric. Therefore, absolute pressure is equal to atmospheric pressure plus gage pressure. For example, 100 psi gage pressure (psig--meaning pounds per square inch gage) equals 100 psi plus 14.7 psi or 114.7 psi absolute pressure (psia--meaning pounds per square inch absolute).

INCOMPRESSIBILITY AND EXPANSION OF LIQUIDS

Liquids can be only slightly compressed; that is, the reduction of the volume which they occupy, even under extreme pressure, is very small. If a pressure of 100 psi is applied to a body of water, the volume will decrease only 3/10,000 of its original volume. It would take a force of 32 tons to reduce its volume 10 percent. Since other liquids behave in about the same manner, liquids are usually considered incompressible.

NOTE: In some applications of hydraulics where extremely close tolerances are required,

12903

the compressibility of liquids must be considered in the design of the system. In this course, however, liquids are considered to be incompressible.

Liquids usually expand when heated. This action is normally referred to as thermal expansion. All liquids do not expand the same amount for a certain increase in temperature. If two flasks are placed in a heated vessel, and if one of these flasks is filled with water and the other with alcohol, it will be found that the alcohol expands much more than the water for the same rise in temperature. Most oils expand more than water. Hydraulic systems contain provisions for compensating for this increase of volume in order to prevent breakage of the equipment.

COMPRESSIBILITY AND EXPANSION OF GASES

The two major differences between gases and liquids are in respect to compressibility and expansion. While liquids are practically incompressible, gases are highly compressible. Gases tend to completely fill any closed vessel in which they are contained, while liquids fill a container only to the extent of their normal volume.

Kinetic Theory of Gases

The simple structure of gases makes them readily adaptable to mathematical analysis from which has evolved a detailed theory of the behavior of gases. This is called the kinetic theory of gases. The theory assumes that a body of gas is composed of identical molecules which behave like minute elastic spheres, spaced relatively far apart and continuously in motion.

The degree of molecular motion is dependent upon the temperature of the gas. Since the molecules are continuously striking against each other and against the walls of the container, an increase in temperature with the resulting increase in molecular motion causes a corresponding increase in the number of collisions between the molecules. The increased number of collisions results in an increase in pressure because a greater number of molecules strike against the walls of the container in a given unit of time.

If the container were an open vessel, the gas would tend to expand and overflow from the container. However, if the container is sealed and possesses elasticity (such as a rubber balloon), the increased pressure causes the container to expand.

For instance, when making a long drive on a hot day, the pressure in the tires of an automobile increases and a tire which appeared to be somewhat "soft" in cool morning temperature may appear normal at a higher midday temperature.

Such phenomena as these have been explained and set forth in the form of laws pertaining to gases and tend to support the kinetic theory.

At any given instant, some molecules of a gas are moving in one direction, some in another direction; some are traveling fast while some are traveling slowly; some may even be in a state of rest. The combined effect of these varying velocities corresponds to the temperature of the gas. In any considerable amount of gas, there are so many molecules present that in accordance with the "laws of probability" some average velocity can be found which, if it were possessed by every molecule in the gas, would produce the same effect at a given temperature as the total of the many varying velocities.

Boyle's Law

As previously stated, compressibility is an outstanding characteristic of gases. The English scientist Robert Boyle was among the first to study this characteristic which he called the "springiness of air." By direct measurement he discovered that when temperature of an enclosed sample of gas was kept constant and the pressure doubled, the volume was reduced to half the former value; as the applied pressure was decreased, the resulting volume increased. From these observations, he concluded that for a constant temperature the product of the volume and pressure of an enclosed gas remains constant. Boyle's law is normally stated: "The volume of an enclosed dry gas varies inversely with its pressure, provided the temperature remains constant."

This law can be demonstrated by confining a quantity of gas in a cylinder which has a tightly fitted piston. A force is then applied to the piston so as to compress the gas in the cylinder to some specific volume. When the force applied to the piston is doubled, the gas is compressed to one-half its original volume, as indicated in figure 2-9.

12904

Figure 2-9.—Gas compressed to half its original volume by a double force.

In equation form, this relationship may be expressed either

$$V_1 P_1 = V_2 P_2$$

$$\text{or } \frac{V_1}{V_2} = \frac{P_2}{P_1}$$

when V_1 and P_1 are the original volume and pressure, and V_2 and P_2 are the revised volume and pressure.

Example of Boyle's law: 4 cubic feet of nitrogen are under a pressure of 100 psi (gage). The nitrogen is allowed to expand to a volume of 6 cubic feet. What is the new gage pressure? Remember to convert gage pressure to absolute pressure by adding 14.7.

Formula or equation:

$$V_1 P_1 = V_2 P_2$$

Substituting:

$$4 \times (100 + 14.7) = 6 \times P_2$$

$$P_2 = \frac{4 \times 114.7}{6}$$

$$P_2 = 76.47 \text{ psi absolute}$$

Converting absolute pressure to gage pressure:

76.47
-14.7
61.77 psi gage pressure—Answer.

A gas which conforms to Boyle's law is termed an ideal gas. When pressure is increased upon such a gas, its volume decreases proportionally and its density is increased. So it follows that the density of a gas varies directly as the pressure, if the temperature remains constant as in the case of an ideal gas. Density also varies with temperature, since gases expand when heated and contract when cooled.

Charles' Law

The French scientist Jacques Charles provided much of the foundation for the modern kinetic theory of gases. He found that all gases expand and contract in direct proportion to the change in the absolute temperature, provided the pressure is held constant. Expressed in equation form, this part of the law may be expressed.

$$V_1 T_2 = V_2 T_1,$$

$$\text{or } \frac{V_1}{V_2} = \frac{T_1}{T_2}$$

where V_1 and V_2 refer to the original and final volumes, and T_1 and T_2 indicate the corresponding absolute temperatures.

Since any change in the temperature of a gas causes a corresponding change in volume, it is reasonable to expect that if a given sample of a gas were heated while confined within a given volume, the pressure should increase. By actual experiment, it was found that the increase in pressure was approximately 1/273 of the 0° C pressure for each 1° C increase. Because of this fact, it is normal practice to state this relationship in terms of absolute temperature. In equation form, this part of the law becomes

$$P_1 T_2 = P_2 T_1,$$

$$\text{or } \frac{P_1}{P_2} = \frac{T_1}{T_2}$$

In words, this equation states that with a constant volume, the absolute pressure of a gas varies directly with the absolute temperature.

Examples of Charles' Law: A cylinder of gas under a pressure of 1,800 psig at 70° F is left out in the sun in the tropics and heats up to a

12905

temperature of 130° F. What is the new pressure within the cylinder? The pressure and temperature must be converted to absolute pressure and temperature.

Formula or equation:

$$\frac{P_1}{P_2} = \frac{T_1}{T_2}$$

Using the Rankine system:

$$70°F = 530° \text{ absolute}$$
$$130° F = 590° \text{ absolute}$$

Substituting:

$$\frac{1{,}800 + 14.7}{P_2} = \frac{530}{590}$$

Then:

$$P_2 = \frac{(590)\ (1{,}814.7)}{530}$$

$$P_2 = 2{,}020 \text{ psia}$$

Converting absolute pressure to gage pressure:

$$\begin{array}{r} 2{,}020.0 \\ -14.7 \\ \hline 2{,}005.3 \end{array} \text{ psig—Answer.}$$

General Gas Law

The facts concerning gases discussed in the preceding sections are summed up and illustrated in figure 2-10. Boyle's law is expressed in (A) of the figure, while the effects of temperature changes on pressure and volume (Charles' law) are illustrated in (B) and (C), respectively.

By combining Boyle's and Charles' law, a single expression can be derived which states all the information contained in both. This expression is called the GENERAL GAS LAW, a very useful form of which is given in the following equation. (NOTE: The capital P and T signify absolute pressure and temperature, respectively.)

$$\frac{P_1\ V_1}{T_1} = \frac{P_2\ V_2}{T_2}$$

Figure 2-10.—The general gas law.

It can be seen by examination of figure 2-10 that the three equations are special cases of the general equation. Thus, if the temperature remains constant, T_1 equals T_2 and both can be eliminated from the general formula, which then reduces to the form shown in (A). When the volume remains constant, V_1 equals V_2, thereby reducing the general equation to the form given in (B). Similarly P_1 is equated to P_2 for constant pressure, and the equation then takes the form given in (C).

The general gas law applies with exactness only to "ideal" gases in which the molecules are assumed to be perfectly elastic. However, it describes the behavior of actual gases with sufficient accuracy for most practical purposes.

Two examples of the general equation follow:

1. Two cubic feet of a gas at 75 psig and 80° F are compressed to a volume of 1 cubic foot and then heated to a temperature of 300° F. What is the new gage pressure?

Formula or equation:

$$\frac{P_1\ V_1}{T_1} = \frac{P_2\ V_2}{T_2}$$

Using the Rankine system:

$$80° F = 540° \text{ absolute}$$
$$300° F = 760° \text{ absolute}$$

Substituting:

$$\frac{(75 + 14.7)\ (2)}{540} = \frac{P_2\ (1)}{760}$$

12906

D. Eyestrain. Both eyes should be kept open when looking through the microscope. If one eye is kept closed while using the other to look through the microscope, the eye muscles will tire. Imperfect focusing will also cause eye strain.

E. Cleaning the lenses. Always use lens paper to clean the lens. Hold the lens paper against the lens and twist slightly. You should NEVER rub heavily, it may scratch the lens. Do not use cloth or tissue paper to clean the lens, they may contain grit that would damage the lens.

2. Diversity and Ubiquity of Microorganisms

OBJECTIVES: To show (1) that the atmosphere, under most circumstances, contains an abundance and diversity of microorganisms; (2) that the population varies from time to time, and from situation to situation; and (3) that microorganisms in the air may be isolated by suitable culture techniques.

MATERIALS: PDA; nutrient agar; water agar; petri dishes; nitrient broth; flasks; transfer needles.

PROCEDURES: Depending on the time available, solid and liquid media can be prepared as a part of the exercise or provided at the outset. If the media are prepared, the instructor can, as he wishes, demonstrate the use of the hot-air sterilizer, autoclave, etc. As an added feature of this particular exercise, if time permits, any one or more of the routine steps may be omitted purposely and the effect thereof on the end result noted; i.e., sterilization of the media or of the petri dishes might be omitted.

Select a number of petri dishes of PDA (favoring growth of filamentous fungi) and of nutrient agar (favoring growth of bacteria). The number used will depend on facilities available, number of persons involved, and the number of situations to be tested.

Expose plates of each medium for varying lengths of time not only in the laboratory, but in sites that are as diverse as practicable, such as garden, grocery store, kitchen, outdoors in shelter of shrubs, etc. If at all possible, expose plates at different times of day at the same situation, such as early morning and afternoon; or expose plates under very different weather conditions outdoors, such as on a windy day in the afternoon and early the following morning, if still and foggy.

Details of the experiment will vary greatly, but the main objective will be achieved if sufficiently diverse samples are made and if careful records are kept so that the exposed dishes may be identified during the period of incubation. In each situation there should be at least one dish not exposed and held as a control.

Incubate exposed dishes at room temperature and examine at intervals of 3-4 days. Make records of the number and diversity of bacteria and fungi which appear. If desired, these examinations may include microscopic examination and preliminary or provisional identifications can be made by reference to Barnett (1960).

Then:

$$\frac{179.4}{540} = \frac{P_2}{760}$$

$$P_2 = \frac{(179.4)\ (760)}{540}$$

$$P_2 = 252.5 \text{ psia}$$

Converting absolute pressure to gage pressure:

$$\begin{array}{r} 252.5 \\ -14.7 \\ \hline 237.8 \end{array} \text{ psig --Answer.}$$

2. Four cubic feet of a gas at 75 psig and 80° F are compressed to 237.8 psig and heated to a temperature of 300° F. What is the volume of the gas resulting from these changes?

Formula or equation:

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2}$$

Using the Rankine system:

$$80° \text{ F} = 540° \text{ absolute}$$

$$300° \text{ F} = 760° \text{ absolute}$$

Substituting:

$$\frac{(75 + 14.7)\ (4)}{540} = \frac{(237.8 + 14.7)\ V_2}{760}$$

Then:

$$\frac{(89.7)\ (4)}{540} = \frac{(252.5)\ v_2}{760}$$

$$V_2 = \frac{358.8 \times 760}{540 \times 252.5}$$

$$V_2 = 2 \text{ cubic feet--Answer.}$$

Avogadro's Law

An Italian physicist, Avogardo, conceived the theory that "at the same temperature and pressure, equal volumes of different gases contain equal numbers of molecules." This theory was proven by experiment and found to agree with the kinetic theory, so it has come to be known as Avogadro's law.

Dalton's Law

If a mixture of two or more gases which do not combine chemically is placed in a container, each gas expands throughout the total space and the absolute pressure of each gas is reduced to a lower value, called its partial pressure. This reduction is in accordance with Boyle's law. The pressure of the mixed gases is equal to the sum of the partial pressures. This fact was discovered by Dalton, an English physicist, and is set forth in Dalton's law which states that "a mixture of several gases which do not react chemically exerts a pressure equal to the sum of the pressures which the several gases would exert separately if each were allowed to occupy the entire space alone at the given temperature."

TRANSMISSION OF FORCES THROUGH FLUIDS

When the end of a bar is struck, the main force of the blow is carried straight through the bar to the other end. (See fig. 2-11 (A).) This happens because the bar is rigid. The direction of the blow almost entirely determines the direction of the transmitted force. The more rigid the bar, the less force is lost inside the bar or transmitted outward at right angles to the direction of the flow.

When a force is applied to the end of a column of confined liquid (fig. 2-11 (B)) it is transmitted straight through to the other end and also equally and undiminished in every direction throughout the column--forward, backward, and sideways--so that the containing vessel is literally filled with pressure.

If a gas is used instead of a liquid, the force is transmitted in the same manner. The one difference is that gas, being compressible, provides a much less rigid force than the liquid which is incompressible. (This is the main difference in the action of liquids and gases in fluid power systems.)

An example of this distribution of force is illustrated in figure 2-12. The flat hose takes on a circular cross section when it is filled

12907

Figure 2-11.—Transmission of force; (A) Solid; (B) fluid.

Figure 2-12.—Distribution of force.

with water under pressure. The outward push of the water is equal in every direction. The automobile tire and the toy balloon are examples of this distribution of force through the use of gases.

PASCAL'S LAW

The foundations of modern hydraulics, and pneumatics, were established in 1653 when Pascal discovered that pressure set up in a fluid acts equally in all directions. This pressure acts at right angles to containing surfaces. Thus in figure 2-13, if the liquid standing on a square inch (A) at the bottom of the tank weighs 8 pounds, a pressure of 8 psi is exerted in every direction at (A). The liquid resting on (A) pushes equally downward and outward. The liquid on every square inch of the bottom surface is pushing downward and outward in the same way, so that the pressures on different areas are in balance. At the edge of the bottom the pressures act against the wall of the tank, which must be strong enough to resist them with a force exactly equal to the push. Every square inch of the bottom of the tank must also be strong enough to resist the downward pressure of the liquid resting on it. The same balance of pressures exists at every other level in the tank, though of lesser pressures as one approaches the surface. Therefore, the liquid remains at rest--it does not leak out and the tank does not collapse.

One of the consequences of Pascal's law is that the shape of the container in no way alters pressure relations. Thus in figure 2-14, if the pressure due to the weight of the liquid at one point on the horizontal line (H) is 8 psi, the pressure is 8 psi everywhere at level (H) in the system.

Figure 2-13.—Pressure acting on a container.

12908

Figure 2-14.—Pressure relationship with shape.

Pressure due to the weight of a fluid depends, at any level, upon the vertical height of the fluid from the level to the surface of the fluid. The vertical distance between two horizontal levels in a fluid is known as the head of the fluid. In figure 2-14, the liquid head of all points on level (H) with respect to the surface is indicated.

Pressure due to fluid head also depends upon the density of the fluid. Water, for example, weighs 62.4 pounds per cubic foot or 0.036 pound per cubic inch, while certain oil might weigh 55 pounds per cubic foot, or 0.032 pound per cubic inch. It would take 222 inches of head, using water, to produce a pressure of 8 psi and 252 inches using the oil. (See fig. 2-15.)

This pressure head also exists with the use of gases. However, a cubic foot of air at 70° F and under a pressure of 100 psi produces a pressure head which is less than 1 percent of that produced by a cubic foot of water.

Figure 2-15.—Pressure and density relationship.

FORCE AND PRESSURE

In order to understand how Pascal's principle is applied to fluid power, a distinction must be made between the terms force and pressure. Force may be defined as a push or pull. It is the push or pull exerted against the total area of a particular surface and is expressed in pounds. As previously stated, pressure is the amount of force on a unit area of the surface acted upon. In hydraulics and pneumatics, this unit area is expressed in pounds per square inch. Thus, pressure is the amount of force acting upon 1 square inch of area.

DIBGL
12909

Computing Force, Pressure, and Area

A formula, similar to those used in conjunction with the gas laws, is used in computing force, pressure, and area in fluid power systems. Although there appears to be three formulas, there is only one formula written in three variations where P refers to pressure, F indicates force, and A represents area.

Force equal pressure times area. Thus, the formula is written

$$F = P \times A$$

Pressure equals force divided by the area. By rearranging the formula, this statement may be condensed into

$$P = \frac{F}{A}$$

Since area equals force divided by pressure, the formula is written

$$A = \frac{F}{P}$$

Figure 2-16 illustrates a device for recalling these formulas. Any letter in the triangle may be expressed as the product or quotient of the other two, depending upon its position within the triangle.

For example, to find area, consider the letter A as being set off to itself, followed by an equal sign. Now look at the other two letters. The letter F is above the letter P; therefore, $A = \frac{F}{P}$.

In order to find pressure, consider the letter P as being set off to itself, and look at the other two letters. The letter F is above the letter A; therefore, $P = \frac{F}{A}$.

Likewise, to find force, consider the letter F as being set off to itself. The letters P and A are side by side, therefore, $F = P \times A$.

NOTE: Sometimes the area may not be expressed in square inches. If it is a rectangular surface, the area may be found by multiplying the length (in inches) by the width (in inches). The majority of areas to be considered in these calculations are circular in shape. Either the radius or the diameter may be given. The radius in inches must be known to find the area. The radius is one-half the diameter. Then,

Figure 2-16.—Device for determining the arrangement of the force, pressure, and area formula.

the formula for finding the area of a circle is used. This is written $A = \pi r^2$, where, A is the area, π is 3.1416 (3.14 or 3 1/7 for most calculations), and r^2 indicates radius squared.

PRESSURE AND FORCE IN FLUID POWER SYSTEMS

In accordance with Pascal's law, any force applied to a confined fluid is transmitted equally in all directions throughout the fluid regardless of the shape of the container. Consider the effect of this in the system shown in figure 2-17. This is in reality a modification of figure 2-11 (B) in which the column of fluid is curved back upward to its original level, with a second piston at this point. It is clear that when the input piston (1) is pushed downward, a pressure is created through the fluid, which acts equally at right angles to surfaces in all parts of the container.

Referring to figure 2-17, if the force (1) is 100 pounds and the area of the piston is 10 square inches, then the pressure in the fluid is 10 psi $\left(\frac{100}{10}\right)$. This pressure acts on piston (2), so that for each square inch of its area it is pushed upward with a force of 10 pounds. In this case, a fluid column of uniform cross section is considered so that the area of the output piston (2) is the same as the input piston (1), or 10 square inches. Therefore, the upward force on the output piston (2) is 100 pounds, the same as was applied to the input piston (1). All that has been accomplished in this system was to transmit the 100-pound force around a bend. However, this principle underlies practically all mechanical applications of fluid power.

At this point it should be noted that since Pascal's law is independent of the shape of the

12910

Figure 2-17.—Force transmitted through fluid.

container, it is not necessary that the tube connecting the two pistons should be the full area of the pistons. A connection of any size, shape, or length will do, so long as an unobstructed passage is provided. Therefore, the system shown in figure 2-18, wherein a relatively small, bent pipe connects two cylinders, will act exactly the same as that shown in figure 2-17.

Multiplication of Forces

In figures 2-17 and 2-18 the systems contain pistons of equal area wherein the output force is equal to the input force. Consider the situation in figure 2-19, where the input piston is much smaller than the output piston. Assume that the area of the input piston (1) is 2 square inches. Pushing down on the input piston (1) with a force of 20 pounds creates 10 psi $\left(\frac{20}{2}\right)$ in the fluid. Although this force is much smaller than the applied force in figures 2-17 and 2-18, the pressure is the same. This is because the force is concentrated on a relatively small area.

This pressure of 10 psi acts on all parts of the fluid container, including the bottom of the output piston (2). The upward force on the output piston (2) is therefore 10 pounds for each of its 20 square inches of area, or 200 pounds (10 x 20). In this case, the original force has been multiplied tenfold while using the same pressure in the fluid as before. Obviously, the system would work just the same for any other forces and pressures, so that the ratio of output force to input force is always ten to one.

The system works the same in reverse. Consider piston (2) as the input and piston (1) as the output. Then the output force will always be one-tenth the input force. Sometimes such results are desired.

Therefore, if two pistons are used in a fluid power system, the force acting on each is directly proportional to its area, and the magnitude of each force is the product of the pressure and its area.

Differential Areas

Consider the special situation shown in figure 2-20. Here, a single piston (1) in a cylinder (2) has a piston rod (3) attached to one side of the piston which extends out of the cylinder at one end. Fluid under pressure is admitted to both ends of the cylinder equally through the pipes (4, 5, and 6). The opposed faces of the piston (1) behave like two pistons acting against each other. The area of one face is the full area of the cylinder, say 6 square inches, while the area of the other face is the area of the cylinder minus the area of the piston rod, which is 2 square inches, leaving an effective area of 4 square inches on the right face of the piston. The pressure on both faces is the same, in this case, 20 psi. Applying the rule just stated, the force pushing the piston to the right is its area times the pressure, or 120 pounds (20 x 6). Likewise, the force pushing it to the left is its area times the pressure, or 80 pounds. Therefore, there is a net unbalanced force of 40 pounds acting to the right, and the piston will move in that direction. The net effect is the same as if the piston and cylinder

12911

Figure 2-18.—Transmitting force through small pipe.

Figure 2-19.—Multiplication of forces.

were just the size of the piston rod, since all other forces are in balance.

Volume and Distance Factors

In the systems illustrated in figures 2-17 and 2-18, the pistons have areas of 10 square inches each. Therefore, if one of these pistons is pushed down 1 inch, 10 cubic inches of fluid is displaced. Since liquid is practically incompressible, this volume must go some place. In the case of a gas, it will compress momentarily, but will eventually expand to its original volume. Thus, this volume moves the other piston. Since the area of this piston is likewise 10 square inches it will move 1 inch in order to accommodate the 10 cubic inches of fluid. The pistons are of equal areas, and will therefore

move equal distances, though in opposite directions.

Applying this reasoning to the system in figure 2-19, it is obvious that if the input piston (1) is pushed down 1 inch, only 2 cubic inches of fluid is displaced. In order to accommodate these 2 cubic inches of fluid the output piston (2) will have to move only one-tenth of an inch, because its area is 10 times that of the input piston (1). This leads to the second basic rule for two pistons in the same fluid power system, which is that the distances moved are inversely proportional to their areas.

Effects of Atmospheric Pressure

Atmospheric pressure, described previously, obeys Pascal's law the same as pressure set up in fluids. As illustrated in figure 2-13, pressures, due to liquid head, are distributed equally in all directions. This is also true of atmospheric pressures. The situation is the same if these pressures act on opposite sides of any surface, or through fluids. In figure 2-21 (A) the suspended sheet of paper is not torn by atmospheric pressure, as it would be by an unbalanced force of 14.7 psi, because atmospheric pressure acts equally on both sides of the paper. In figure 2-21 (B), atmospheric pressure acting on the surface of the liquid is transmitted equally throughout the liquid to the walls of the container, but is balanced by the same pressure acting directly on the outer walls of the container. In figure 2-21 (C), atmospheric pressure acting on the surface of one piston is balanced by the same pressure acting on the surface of the other. The different areas of the two surfaces make no difference, since for a unit of area, pressures are in balance.

Vacuum and Partial Vacuum

When an individual drinks soda through a straw, he removes some of the air from the straw. This disturbs the balance of pressures which was prevailing between the liquid in the glass and the liquid in the straw. This results in an unbalance of pressures, and atmospheric pressure on the liquid in the glass pushes the soda up into the straw until a new balance is reached. The soda can be held at a certain level in the straw. This level will always be where the pressure of the head of liquid exactly equals the difference between the pressure in the straw and that on the surface on the liquid in the glass. (See fig. 2-22.) When the straw is removed from the person's mouth, the soda in the straw is subject to the same pressure as that on the surface of the liquid in the glass. This causes the liquid in the straw to return to its original level which is the same as that in the glass.

A partial vacuum is produced in the straw--that is, a pressure less than the prevailing atmospheric pressure. The theoretical limit of this process would be a condition of zero pressure--a complete vacuum. In actual practice, however, it is impossible to produce a complete vacuum.

This action takes place in the power supply for fluid power systems. As the pump or compressor moves the fluid into the system, a low pressure area (partial vacuum) is developed at the inlet port. This allows atmospheric pressure to push fluid into the inlet port of the pump or compressor. This action is discussed in greater detail in chapter 4.

INPUT AND OUTPUT RELATIONS

As illustrated in figure 2-19, an increase in output force over input force is accompanied by a decrease in the distance moved in exactly the same ratio. An increase in force can be obtained only by a proportional decrease in distance moved. This is also true if the system is operated in the reverse direction—a distance increase can be obtained, but only at the expense of a force decrease in the same ratio. This leads to the basic statement: Neglecting friction, in any fluid power system (or any other mechanical system for that matter), the input force multiplied by the distance through which it moves, is always exactly equal to the output force multiplied by the distance through which it moves.

Work and Energy

Work is defined as a force moving through some distance, and the amount of work done is the product of the force multiplied by the distance through which it moves. Therefore, when friction is neglected, the work output is always equal to the work input. Energy is a similar but broader term. Energy includes work and in addition, all the forms into which work can be converted or which can be converted into work. Work always involves actual movement,

1. Piston.
2. Cylinder.
3. Piston rod.
4. Pipe.
5. Pipe.
6. Pipe.

Figure 2-20 .—Differential areas on a piston.

but energy can be at rest and still exist as energy, so long as it is capable of doing work.

Energy can exist in a great many different forms, but they all have one thing in common; they are all interchangeable with each other and with work. The many forms which energy can take and their interchangeability are illustrated by a hydroelectric plant. (See fig. 2-23.) Here, a body of water is held back by a dam. In this case the water represents potential energy, because it is not doing work at the moment, but is capable of doing work if it is released. If an opening is provided, water will rush out in a high velocity jet representing energy of motion or kinetic energy. If this jet is directed against the blades of a water wheel it will push them around producing a continuous rotary motion. This is work in its true sense because a force is moving through a distance.

The water wheel can, in turn, be connected to an electric generator which converts the work into electricity. This electricity can, in turn, be converted back into work by the use of an electric motor; or it can be converted into light by the use of an electric bulb or into heat in an electric iron. By means of a motor and a pump, the energy can be transformed back into its original form of potential energy existing as a body of water at an elevation. Thus, all of these forms of energy are interchangeable with each other. In actual mechanisms, there is always some loss in the form of friction producing heat at every exchange, but the total energy, useful and wasted, will always add up to the original input energy.

For simplicity, friction was disregarded in the preceding discussions. However, it is well known that there is always some friction in actual machines. It is also known that heat is produced whenever work is accomplished against friction. Therefore, heat is a form of energy because it can be produced from work. Likewise heat in the form of fire under a boiler can be converted into work through the medium of a steam engine. Friction represents a loss of efficiency, but this does not

412914

Figure 2-21. Effects of atmospheric pressure.

mean an annihilation of energy itself. It means only that some of the energy put into the system has been converted into another form which is not useful for the particular problem in hand. The energy is not usable or available, but it still exists as dissipated heat.

In agreement with this fact, any work or energy added to the system must in turn come from somewhere else, for it is not possible to create or destroy energy. All that can be done is to change it from one form into other forms, so as to make it more or less applicable to the purposes at hand. In the case of a hydraulic jack, since there is always some friction both within the liquid and between adjacent parts, the useful work output will not exactly equal the work input, but the difference will always exist somewhere in some other form of energy. In this case it will appear as heat which must escape from the system somewhere at some time. In other words, while the usable work output does not equal the input, the total energy output in all forms will always exactly equal the total energy input. This is known as the law of the conservation of energy.

Work and Power

Work and energy are measured in the same units, the foot-pound in the English system and the gram-centimeter in the metric system. Power is the rate of doing work. The same amount of work may be accomplished in two instances but less time is used in one case

12915

Figure 2-22.—Partial vacuum.

than in the other. More power is required where less time is used. The unit for the English system is the horsepower, which is at the rate of 33,000 foot-pounds per minute or 550 foot-pounds per second. The metric system uses the centimeter-gram per second as its unit of measurement.

FLUID FLOW

In order to understand fluid power systems in action, it is necessary to become acquainted with some of the elementary characteristics of fluids in motion. Among these are volume and velocity of flow, steady and unsteady flow, streamline and turbulent flow, and, even more important, the force and energy changes that occur in flow and the relations of different kinds of energy to each other in fluid power systems.

Under normal working conditions the fluid in a fluid power system is under pressure and completely fills the pipes of the system. This pressure is due in part to the force of gravity or weight of the fluid, and in part to externally applied forces such as might result from the action of a pump or compressor, which, in turn, might have energy supplied to it by an electric motor.

VOLUME AND VELOCITY OF FLOW

The quantity of fluid that passes a given point in a fluid power system in a unit of time is referred to as the volume of flow. Volume of flow can be stated in a number of ways; as for example, 100 cubic feet per minute, 100 gallons per minute or hour, etc. Gallons per minute is the usual method of expressing volume of flow in hydraulic systems, while cubic feet per minute is common in pneumatic systems.

Velocity of flow means the rate or speed at which the fluid moves forward at a particular point in the system. It too can be variously stated, but the usual method is in feet per second.

Volume and velocity of flow are often considered together. With other conditions unaltered—that is, with volume of input unchanged—the velocity of flow increases as the cross section or size of the pipe decreases, and the velocity of flow decreases as the cross section area increases. In a stream, velocity of flow is slow at wide parts of the stream and rapid at narrow parts even though the volume of water passing each part of the stream is the same. In figure 2-24, if the cross-sectional area of the pipe is 16 square inches at point (A) and 4 square inches at point (B), the velocity of flow at (B) is four times the velocity at (A).

STEADY AND UNSTEADY FLOW

A fluid may flow as a single continuous stream, or the volume of flow may increase, decrease, or fluctuate from moment to moment. Such changes in volume constitute unsteady flow. For example, when a faucet is first opened, the initial flow is unsteady during the short time that the rate of flow of the water is increasing from the initial zero rate to the full rate of flow. The flow then becomes steady and is maintained if the pressure remains constant. If the pressure changes, the rate of flow once more becomes unsteady until a new balance is reached.

STREAMLINE AND TURBULENT FLOW

At quite low velocities or in tubes of small diameter, flow is streamline, meaning that a given particle of fluid moves straight forward without crossing the paths followed by other particles, and without bumping into them. Streamline flow is often referred to as laminar flow which is defined as a flow situation in which fluid moves in parallel lamina or layers. As an example of streamline flow, consider figure 2-25, which illustrates an open stream flowing at

Comparison should be made on the basis of the samples taken and between media used. If desired, water agar can be used, in addition to the PDA and nutrient agars, as a demonstration that the presence of organisms can be detected easily only if conditions are favorable for their development into visible colonies. Also, by substituting broth for a solid medium, it can be shown that the diversity of organisms is demonstrable only if the medium selected permits growth of isolated colonies rather than a heterogeneous mixture. It can also be pointed out that only a solid medium permits any estimate of the relative numbers or organisms in the test sites.

TIME REQUIRED: Depending on variable included, 2-3 hours for exposure; 3 to 4 days for growth of colonies of bacteria and fungi.

RESULTS: If any of the initial steps in preparation of media are intentionally omitted, contamination will develop in the eventual plates without their being exposed.

If exposure sites are well chosen, this experiment will show: (1) the abundance of organisms in the environment; (2) variations in numbers and types from one place to another and from one time to another in the same site; (3) diversity of both bacterial and fungal organisms; and (4) the efficiency of solid media as a means of sampling the microflora of the atmosphere.

3. Relation of Wounds to Decay of Citrus Fruit by *Penicillium* sp.

OBJECTIVE: To demonstrate essentiality of wounds for infection of plant tissues with *Penicillium* sp.

MATERIALS: Oranges with blue mold; culture of *Penicillium* sp., healthy oranges; moist chambers.

PROCEDURES: Inoculate healthy orange with *Penicillium* by transferring discernible amounts of culture material (1) to intact surfaces, (2) into cuts in the rind but not down into the juice sacs, and (3) into cuts made down into the juice sacs. Repeat 1, 2, and 3 using scraping from obviously molded portions of rotted citrus fruit.

One fruit may serve for more than one inoculation by using marked portions of the fruit. Place inoculated fruit in moist chambers and observe for decay.

TIME REQUIRED: 1 hour to prepare material and make inoculations, 4 to 5 days to observe results.

RESULTS: Decay will occur only in those fruits in which wounds have been made. This exercise illustrates that wounded tissue is essential for a weak pathogen such as Penicillium to initiate infection and cause decay of citrus fruit.

4. Effect of Temperature on Fungi and Effect of Injury on Fruit Rots

OBJECTIVE: Demonstrate the effect of temperature on fungus growth and the effect of injury on invasion by fungi.

Figure 2-23.—Potential and kinetic energy.

Figure 2-24.—Volume and velocity of flow.

a slow uniform rate with logs floating on its surface. The logs represent particles of fluid. So long as the stream flows along at a slow uniform rate, each log floats downstream in its own path, without crossing or bumping into the other.

If the stream narrows, however, and the volume of flow remains the same, the velocity of flow increases. If the velocity increases sufficiently, the water becomes turbulent. (See fig. 2-26.) Swirls, eddies, and cross-motions are set up in the water. As this happens, the

81652917

Figure 2-25.—Streamline flow.

Figure 2-26.—Turbulent flow.

logs are thrown against each other and against the banks of the stream, and the paths followed by different logs will cross and recross.

Particles of fluid flowing in pipes act in the same manner. The flow is streamline if the fluid flows slowly enough, and remains streamline at greater velocities if the diameter of the pipe is small. If the velocity of flow or size of the pipe increases sufficiently, the flow becomes turbulent.

One effect of turbulent flow is illustrated in figure 2-27, where the length of the horizontal arrows indicates the relative velocities of flow at different places in the pipe, from the center to the edge, when the flow is streamline and when the flow is turbulent. In both instances the rate of flow varies from the center of the pipe to the edge, but streamline flow varies more in velocity than turbulent flow. For streamline flow the average velocity is about one-half the maximum velocity, while for turbulent flow it is about four-fifths. Velocity of flow varies both vertically and horizontally, or from the center of the pipe outward. In both streamline and turbulent flow, the fluid next to the wall of the pipe has little or no velocity.

While a high velocity of flow will produce turbulence in any pipe, other factors contribute to turbulence. Among them are the roughness of pipe, obstructions, and the degree of curvation of bends and the number of bends in the pipe. In setting up or maintaining fluid power systems, care should be taken to eliminate or minimize as many causes of turbulence as possible, since the energy consumed by turbulence is wasted. Limitations as to the degree and number of bends of pipe are discussed in chapter 5.

While designers of fluid power equipment do what they can to minimize turbulence, to a very considerable extent it cannot be avoided.

reel 12918

Figure 2-27.—Streamline versus turbulent flow.

Thus, in a 4-inch pipe at 68° F, flow becomes turbulent at velocities over approximately 6 inches per second or about 3 inches per second for a 6-inch pipe. These velocities are far below those commonly encountered in fluid power systems, where velocities of 5 feet per second and above are frequent. In streamline flow, losses due to friction increase directly with velocity, while with turbulent flow these losses increase much more rapidly.

FACTORS INVOLVED IN FLOW

An understanding of the behavior of fluids in motion, or solids for that matter, requires an understanding of the term "inertia." Inertia is the term used by scientists to describe that property possessed by all forms of matter which makes the matter resist being moved if it is at rest, and likewise, resist any change in its rate of motion if it is moving.

The basic statement covering the action of inertia is: "A body at rest tends to remain at rest, and a body in motion tends to continue in motion with the same velocity and in the same direction." This is simply saying in more scientific terms what everyone has learned by experience—that one must push an object to start it moving and offer an opposition to stop it again.

A familiar illustration is the effort a pitcher must exert to make a fast pitch and the opposition the catcher must put forth to stop the ball. Similarly, considerable work must be performed by the engine to make an automobile begin to roll; although, after it has attained a certain velocity, it will roll along the road at uniform speed if just enough effort is expended to overcome friction, while brakes are necessary to stop its motion. Inertia also explains the kick or recoil of guns and the tremendous striking force of projectiles.

Inertia and Force

In order to overcome this tendency to resist any change in its state of rest or motion, some force which is not otherwise canceled or unbalanced must act upon the object. Some unbalanced force must be applied whenever fluids are set in motion or increased in velocity; while conversely, forces are made to do work elsewhere whenever fluids in motion are retarded or stopped.

Ignoring friction, if the force (A) in figure 2-28 produces a velocity of 10 miles per hour (mph) when it is applied to a body for 5 seconds, it will produce a velocity of 20 mph when it is applied for 10 seconds. The same result of 20 mph would be obtained if a force (B) equal to twice (A) was applied to the body for 5 seconds. Again ignoring friction, the body would be returned to rest from a velocity of 20 mph if force (C), equal to (A) but acting in the opposite direction, was applied to it for 10 seconds, or if a force (D) equal to twice (C) was applied to it for 5 seconds.

There is a direct relationship between the magnitude of the force exerted and the inertia against which it acts. This force is dependent on two factors—on the mass of the object (which is proportional to its weight), and on the rate at which the velocity of the object is changed. The rule is that the force in pounds required to overcome inertia is equal to the weight of the object, multiplied by the change in velocity measured in feet per second, and divided by 32.2 times the time in seconds required to accomplish the change. Thus, the rate of change in

12910

Figure 2-28.—Force and velocity.

velocity of an object is proportional to the force applied. The number 32.2 appears because it is the conversion factor between weight and mass.

As discussed previously, fluids are always acted upon by the force of gravity, or in other words, by their own weight. Also previously explained, is the fact that fluids are acted upon by atmospheric pressure, or the weight of air over the system, if they are exposed to it—if, that is, the system is not completely enclosed. The action of specific applied force was also explained, and, in addition, it was brought out that whenever there is movement there is always some friction. Inertia, just described, completes the list of forces which control the action of fluids in motion.

There are five physical factors which can act upon a fluid to affect its behavior. All of the physical actions of fluids in all possible systems are determined by the relationships of these five factors to each other. Summarizing, these five factors are as follows:

1. Gravity, which acts at all times upon all bodies, regardless of other forces.
2. Atmospheric pressure, which acts when any part of a system is exposed to the open air.
3. Specific applied forces, which may or may not be present, but which, in any event, are entirely independent of the presence or absence of motion.
4. Inertia, which comes into play whenever there is a change from rest to motion or the opposite, or whenever there is a change in direction or in rate of motion.
5. Friction, which is always present whenever there is motion.

Figure 2-29 illustrates a possible relationship of these factors with respect to a particle of fluid (P) in a system. The different forces are shown in terms of head, or in other words, in terms of vertical columns of fluid required to provide the forces. At the particular moment under consideration, a particle of water (P) is being acted upon by an applied force equivalent to a head (A), by atmospheric pressure to a head (B), and by gravity head (C) produced by the weight of the fluid standing over it. The particle possesses sufficient inertia or velocity head to rise to level (P1), since head equivalent to (F) was lost in friction as (P) passed through the system. Since atmospheric pressure (B) acts downward on the system on both sides, what was gained on one side was lost on the other.

If all the pressure acting on (P) to force it through the nozzle could be recovered in the form of elevation head, it would rise to level (Y).

12920

Figure 2-29.—Physical factors governing fluid flow.

If account is taken of the balance in atmospheric pressure, in a frictionless system, (P) would rise to level (X), or precisely as high as the sum of the gravity head and the head equivalent to the applied force.

Kinetic Energy

It was previously pointed out that a force must be applied to an object in order to impart velocity to it or to increase the velocity it already has. Of necessity the force must act while the object is moving over some distance. It was also previously stated that a force acting over a distance is work, and that work and all forms into which it can be changed are classified as energy. Obviously, then, energy is required to give an object velocity. The greater the energy used, the greater the velocity will be.

Likewise, disregarding friction, for an object to be brought to rest or its motion slowed down, a force opposed to its motion must be applied to it. This force also acts over some distance. In this way energy is given up by the object and delivered in some form to whatever opposes its continued motion. The moving object is therefore a means of receiving energy at one place (where its motion is increased) and delivering it to another point (where it is stopped or retarded). While it is in motion it is said to contain this energy as energy of motion or kinetic energy.

Since energy can never be destroyed, it follows that if friction is disregarded the energy delivered to stop the object will exactly equal the energy which was required to increase its speed. At all times the amount of kinetic energy possessed by an object depends upon its weight and the velocity at which it is moving.

Thus, in figure 2-30, the force (F) is applied to the body (A), which is at rest. Disregarding friction, after it has moved 1 foot it will possess kinetic energy equivalent to 1. During each

Figure 2-30.—Kinetic energy.

USPS 12921

succeeding foot of movement it will gain an equal increment of kinetic energy, so long as the force is applied. If it meets a resistance after moving 5 feet, kinetic energy equivalent to 5 is available to do work. Accelerated motion has been a means of receiving energy while force (F) was applied to (A), and of delivering it to do work at the place (A) reached at that time.

The mathematical relationship for kinetic energy is stated in the rule: "Kinetic energy in foot-pounds is equal to the force in pounds which created it, multiplied by the distance through which it was applied, or to the weight of the moving object in pounds, multiplied by the square of its velocity in feet per second, and divided by 64.4."

The relationship between inertia forces, velocity, and kinetic energy can be illustrated by analyzing what happens when a gun fires a projectile against the armor of an enemy ship. (See fig. 2-31.) The explosive force of the powder in the breach pushes the projectile out of the gun, giving it a high velocity. Because of its inertia the projectile offers opposition to this sudden velocity and a reaction is set up which pushes the gun backward (kick or recoil). The force of the explosion acts on the projectile throughout its movement in the gun. This is force acting through a distance producing work. This work appears as kinetic energy in the speeding projectile. The resistance of the air produces friction, which uses some of the energy and slows down the projectile. Eventually, however, the projectile hits its target and because of the inertia tries to continue moving. The target, being relatively stationary, tends to remain stationary because of its inertia. The result is that a tremendous force is set up which either leads to the penetration of the armor or the shattering of the projectile. The projectile is simply a means of transferring energy, in this instance for a destructive purpose, from the gun to the enemy ship. This energy is transmitted in the form of energy of motion or kinetic energy.

Referring to figure 2-31, the projectile is shown in four different positions: at (A) where it is at rest in the gun, just before firing; at (B), a short distance beyond the muzzle of the gun, when its kinetic energy is at the maximum; at (C), midway in its flight, where friction has used up a portion of its original kinetic energy; and at (D), at the moment of impact, where its kinetic energy is suddenly transformed into work by its inertia and the opposed inertia offered by the target. Energy imparted to the projectile at (A) has been transferred in the form of kinetic energy to do work at (D).

In this diagram no effort has been made to exhibit the magnitude of the force of gravity acting on the projectile. It enters, of course, into the path the projectile takes. This situation differs from that shown in figure 2-30 in which the propelling force was continuously applied throughout the period covered by the diagram, whereas in figure 2-31, the force was applied only while the projectile was moving from (A) to (B).

RELATIONSHIP OF FORCE, PRESSURE, AND HEAD

In dealing with fluids, forces are usually considered in relation to the areas over which they are applied. As previously discussed, a

Figure 2-31.—Relationship of inertia, velocity, and kinetic energy.

1ses1 . 12922

force acting over a unit area is a pressure, and pressures can alternatively be stated in psi or in terms of head, which is the vertical height of the column of fluid whose weight would produce that pressure.

In most of the applications of fluid power in the Navy, applied forces greatly outweigh all other forces, and in most systems the fluid is entirely confined. Under these circumstances it is customary to think of the forces involved in terms of pressures. Since the term head is encountered frequently in the study of fluid power, it is necessary to understand what it means and how it is related to pressure and force.

All five of the factors which control the actions of fluids can, of course, be expressed either as force, or in terms alternatively of equivalent pressures or heads. In each situation, however, the different factors are commonly referred to in the same terms, since on this common basis they can be added and subtracted to study their relationship to each other.

At this point some terms in general use should be reviewed. Gravity head, when it is of sufficient importance to be considered, is sometimes referred to as head. The effect of atmospheric pressure is referred to simply as atmospheric pressure (Atmospheric pressure is frequently and improperly referred to as suction.) Inertia effect, because it is always directly related to velocity, is usually called velocity head, and friction, because it represents a loss of pressure or head, is usually referred to as friction head.

STATIC AND DYNAMIC FACTORS

The first three factors—gravity, applied force, and atmospheric pressure—apply equally to fluids at rest or in motion, while the latter two—inertia and friction—apply only to fluids in motion. The first three are the static factors and the latter two the dynamic factors. The mathematical sum of the first three—gravity, applied force, and atmospheric pressure—is the static pressure obtained at any one point in a fluid at any given time. Static pressure exists in addition to any dynamic factors which may also be present at the same point and time.

Remember, Pascal's law states that a pressure set up in a fluid acts equally in all directions and at right angles to the containing surfaces. This covers the situation only for fluids at rest, or practically at rest. It is true only for the factors making up static head. Obviously, when velocity becomes a factor it must have a direction, and, as previously explained, the force related to the velocity must also have a direction, so that Pascal's law alone does not apply to the dynamic factors of fluid power.

The dynamic factors of inertia and friction are related to the static factors. Velocity head and friction head are obtained at the expense of static head. However, a portion of velocity head can always be reconverted to static head. Force, which can be produced by pressure or head when dealing with fluids, is necessary to start a body moving if it is at rest, and is present in some form when the motion of the body is arrested. Therefore, whenever a fluid is given a velocity, some part of its original static head is used to impart this velocity, which then exists as velocity head.

BERNOULLI'S PRINCIPLE

Consider the system illustrated in figure 2-32. Chamber (A) is under pressure and is connected by a tube to chamber (B), which is also under pressure. The pressure in chamber (A) is static pressure of 100 psi. The pressure at some point (X) along the connecting tube consists of a velocity pressure of 10 psi exerted in a direction parallel to the line of flow, plus the unused static pressure of 90 psi, which still obeys Pascal's law and operates equally in all directions. As the fluid enters chamber (B) it is slowed down, and, in so doing, its velocity head is changed back into pressure head. The force required to absorb its inertia equals the force required to start the fluid moving originally, so that the static pressure in chamber (B) is again equal to that in chamber (A), although it was lower at an intermediate point.

This situation (fig. 2-32) disregards friction, and would therefore not be encountered in actual practice. Force or head is also required to overcome friction, but, unlike inertia effect, this force cannot be recovered again, although the energy represented still exists somewhere as heat. Therefore, in an actual system the pressure in chamber (B) would be less than that in chamber (A) by the amount of pressure used in overcoming friction along the way.

At all points in a system, therefore, the static pressure is always the original static pressure less any velocity head at the point in question, and less the friction head consumed in reaching that point. Since both velocity head

12923

dimensions for the particular conditions is used, and it is installed along as direct a route as possible. Sharp bends and sudden changes in cross sectional area are avoided. Valves, gages, and other components are designed so as to interrupt the flow as little as possible. Careful thought is given to the size and shape of openings. The systems are designed so they can be kept clean inside and so variations from normal operation can easily be detected and remedied.

12925

CHAPTER 3

HYDRAULIC AND PNEUMATIC FLUIDS

During the design of equipment that requires fluid power, many factors must be considered in the selection of the type of system to be used—hydraulic, pneumatic, or a combination of the two. Some of the factors that must be considered are as follows: Required speed and accuracy of operation, surrounding atmospheric conditions, heat, economic conditions, availability of replacement fluid, required pressure level, temperature range, contamination possibilities, cost of transmission lines, limitations of the equipment, lubricity, safety to operators, and expected service life of the equipment.

After the type of system has been selected, many of these same factors must be considered in selecting the fluid for the system, particularly in the selection of a liquid for a hydraulic system.

HYDRAULIC LIQUIDS

Liquids are used in hydraulic systems primarily to transmit and distribute forces to the various units to be actuated. As was pointed out in chapter 2, liquids are able to do this because they are almost incompressible. Pascal's law states that a force applied on any area of an enclosed liquid is transmitted equally and undiminished to all equal areas throughout the enclosure. Thus, if a number of passages exist in a system, pressure can be distributed through all of them by means of the liquid.

Commercial manufacturers of hydraulic devices usually specify the type of liquid best suited for use with their equipment, in view of the working conditions, the service required, temperatures expected inside the systems and out, pressures the liquid must withstand, the possibilities of corrosion, etc. In Navy hydraulic systems, proper specifications are determined by various bureaus on the basis of experiments, tests, and trials. The bureaus experienced many difficulties; for example, in the search for hydraulic liquids adapted to both the subzero Arctic climate and the high temperatures of the Tropics.

PROPERTIES

If incompressibility and fluidity were the only qualities required, any liquid not too thick might be used in a hydraulic system. But a satisfactory liquid for a particular installation must possess a number of other properties. Some of the properties and characteristics that must be considered when selecting a satisfactory liquid for a particular system are discussed in the following paragraphs.

Viscosity

One of the most important properties of the liquid to be used in hydraulic equipment is its viscosity. Viscosity is the internal resistance of a fluid which tends to prevent it from flowing. A liquid, such as gasoline, which flows easily has a low viscosity; and a liquid, such as tar, which flows slowly has a high viscosity. Viscosity increases with decreases in temperature, since liquids flow less easily when cold than when hot.

A satisfactory liquid for a given hydraulic system must have enough body to give a good seal at pumps, valves, and pistons; but must not be so thick that it offers resistance to flow, leading to power loss and higher operating temperatures. These factors will add to the load and to excessive wear of the parts. A fluid that is too thin will also lead to rapid wear of moving parts, or of parts which have heavy loads.

MEASUREMENT OF VISCOSITY.—The viscosity of a liquid is measured with an instrument called a viscosimeter or viscometer. There are several types, but the instrument most often used by American engineers is the Saybolt Universal

12926

MATERIALS: An orange with blue or green mold on it or a mold culture, eight oranges without bruises or soft spots, tweezers, cellophane tape and refrigeration.

PROCEDURES: Divide the good oranges into two groups, "I" and "II". Divide each group into two sub groups, "A" and "B", and from each orange in the "A" sub group cut a 1/4" piece out of the rind with the tweezers and very carefully place some inoculum from the molded orange or the culture into the wound and cover with cellophane tape. The oranges in sub groups "B" are to be inoculated also, being very careful not to injure the surface of the oranges. Cover the spot inoculated with cellophane tape. Then place the 4 oranges in group I in a refrigerator. Put the 4 oranges in group II in a dish and put them in a safe place in your room.

Compare the growth of mold under the different conditions.

TIME REQUIRED: 1 hour to prepare materials and make inoculations, 7 days to observe results.

RESULTS: Compare mold growth according to temperature and to injury of the oranges. This shows that the proper storing temperature and care in handling are both necessary to prevent fruit rots.

RECORD SHEET

1. Answer the following questions:

a) Did mold grow on all 8 oranges?_____ If not, on which ones did it grow? _____

b) Was the fungus growth better on those stored in the refrigerator or those kept in your room? _____

_____

c) What do you think is the reason for these results? _____

_____

_____

d) Was there more fungus growth on the oranges that were injured than on those that were uninjured?_____ Why? _____

_____

_____

_____

1290

Viscosimeter (fig. 3-1). This instrument measures the number of seconds it takes for a fixed quantity of liquid (60 cubic centimeters) to flow through a small orifice of standard length and diameter at a specific temperature. This time of flow is taken in seconds, and the viscosity reading is expressed as Second, Saybolt Universal (SSU). For example, a certain liquid might have a viscosity of 80 SSU at 130° F.

The Saybolt Viscosimeter consists of a reservoir for the liquid surrounded by a bath heated by heating coils to bring the liquid to the temperature at which the viscosity is to be measured. The bottom of the reservoir issues into the standard viscosimeter orifice. Passage through the orifice is blocked by a cork. The reservoir is filled to a marked level with the liquid to be tested and a container marked at the 60-cubic centimeter (cc) level is placed under the opening. When the liquid is at the desired test temperature, the cork is removed, and the number of seconds it takes for the liquid to reach the 60-cc level gives the SSU reading.

VISCOSITY INDEX.—One of the properties of an ideal hydraulic liquid would be that of retaining the same viscosity under all temperature and pressure conditions to which it is subjected. Many liquids, particularly petroleum base oils, do not have this characteristic. As the temperature increases, the oil becomes thinner—the viscosity decreases; as the temperature decreases, the oil thickens—the viscosity increases. The variation is greater for some liquids than for others. Pennsylvania crude oils (paraffinic) vary comparatively little in viscosity with changes in temperature; while with Gulf Coast crudes (naphthenic or asphaltic), the variation is considerably greater.

Figure 3-1.—Saybolt Viscosimeter.

In order to obtain a numerical indication of the degree to which viscosity changes with change in temperatures, these two oils are taken as the basis for a scale. The change in viscosity of a specific paraffinic oil between 100° F and 210° F is assigned a viscosity index (V.I.) value of 100, while the change in viscosity of a specific naphthenic oil over the same temperature range is assigned a value of 0. Other liquids are then assigned a viscosity index in terms of the degree to which their viscosity changes over this range, as compared to the standard oils.

The greater the variation in viscosity with changes in temperature, the lower the V.I. The V.I. figures may range above 100 or below 0, if the liquids being measured vary less or more widely in viscosity than the standard oils. Thus, a liquid with a viscosity index of -10 would vary in viscosity with changes in temperature to an even greater degree than naphthenic oils; while an oil with a viscosity index of 120 would show even less change in viscosity with changes in temperature than paraffinic oils.

Since naval hydraulic systems must work satisfactorily under wide temperature extremes, from Arctic regions to the Tropics and from below sea level to many miles into space, the liquids used should have as high a viscosity index as possible, consistent with the other properties the liquid must possess. The viscosity of a liquid is often increased through the use of chemical additives.

Lubricating Power

If motion takes place between surfaces in contact, friction tends to oppose the motion. When pressure forces the liquid of a hydraulic system between the moving surfaces, the liquid spreads out into a thin film which enables the parts to move more freely. This lubricates the area. Different liquids, including oils vary greatly not only in their lubricating ability, but also in film strength which is the capacity of a liquid to resist being wiped or squeezed out from between the surfaces when spread out in an extremely thin layer. A liquid will no longer lubricate if

12927

the film breaks down, since the motion of part against part wipes the metal clean of liquid. Since lubricating power varies with temperature, climatic and working conditions must enter into the determination of the lubricating qualities of a liquid. Unlike viscosity, which is a physical property, the lubricating power and film strength of a liquid is directly related to its chemical nature. Lubricating qualities and film strength can be improved by the addition of certain chemical agents.

Chemical Stability

Chemical stability is another property which is exceedingly important in the selection of a hydraulic liquid. It is defined as the liquid's ability to resist oxidation and deterioration for long periods. All liquids tend to undergo unfavorable chemical changes under severe operating conditions. This is the case, for example, when a system operates for a considerable period of time at high temperatures.

Excessive temperatures have a great effect on the life of a liquid. It should be noted that the temperature of the liquid in the reservoir of an operating hydraulic system does not always represent a true state of operating conditions. Localized hot spots occur on bearings, gear teeth, or at the point where liquid under pressure is forced through a small orifice. Continuous passage of a liquid through these points may produce local temperatures high enough to carbonize or sludge the liquid, yet the liquid in the reservoir may not indicate an excessively high temperature. Liquids with a high viscosity have a greater resistance to heat than light or low viscosity liquids which have been derived from the same source. The average hydraulic liquid has a low viscosity. Fortunately, there is a wide choice of liquids available for use in the viscosity range required of hydraulic liquids.

Liquids may break down if exposed to air, water, salt, or other impurities, especially if they are in constant motion or subjected to heat. Some metals, such as zinc, lead, brass, and copper, have an undesirable chemical reaction on certain liquids.

These chemical processes result in the formation of sludge, gums, and carbon or other deposits which clog openings, cause valves and pistons to stick or leak, and give poor lubrication to moving parts. As soon as a small amount of sludge or other deposits are formed, the rate of formation generally increases more rapidly. As they are formed, certain changes in the physical and chemical properties of the liquid take place. The liquid usually becomes darker in color, higher in viscosity, and acids are formed.

The extent to which changes occur in different liquids depends on the type of liquid, type of refining, and whether it has been treated to provide further resistance to oxidation. The stability of liquids can be improved by the addition of oxidation inhibitors. Laboratory tests must be conducted to select the type and quantity of the inhibitor most effective against oxidation of a particular liquid. However, inhibitors must also be compatible with the other required properties of the liquid.

Freedom from Acidity

An ideal hydraulic liquid should be free from acids which cause corrosion of the metals in the system. Most liquids cannot be expected to remain completely noncorrosive under severe operating conditions. The degree of acidity of a liquid, when new, may be satisfactory; but after use, the liquid may tend to develop corrosive tendencies as it begins to deteriorate. The liquid must be carefully processed with the specific aim of inhibiting harmful acid formation which would attack metal surfaces in the system.

Many systems are idle for long periods after operating at high temperatures. This permits moisture to be condensed in the system, resulting in rust formation.

Certain corrosion- and rust-preventive additives are added to hydraulic liquids. Some of these additives are effective only for a limited period. Therefore, the best procedure is to use the liquid specified for the system, and to protect the liquid and the system as far as possible from contamination by foreign matter, from abnormal temperatures, and misuse.

Flashpoint

Flashpoint is the temperature at which a liquid gives off vapor in sufficient quantity to ignite momentarily or flash when a flame is applied. A high flashpoint is desirable for hydraulic liquids because it indicates good resistance to combustion and a low degree of evaporation at normal temperatures.

12928

Fire Point

Fire point is the temperature at which a substance gives off vapor in sufficient quantity to ignite and continue to burn when exposed to a spark or flame. Like flashpoint, a high fire point is required of desirable hydraulic liquids.

Minimum Toxicity

Toxicity is defined as the quality, state, or degree of being toxic or poisonous. Some liquids contain chemicals that are a serious toxic hazard. These toxic or poisonous chemicals may enter the body through inhalation, by absorption through the skin, through the eyes, or through the mouth. The result is sickness and in many cases death. Manufacturers of hydraulic liquids strive to produce suitable liquids that contain no toxic chemicals and, as a result, most hydraulic liquids are free of harmful chemicals. Some fire-resistant liquids are toxic, and suitable protection and care in handling must be provided. Containers for toxic liquids must be properly labeled.

NOTE: MIL-STD-755 establishes a uniform design for symbols to warn users of potential hazards involved with the use of materials in containers. The toxic symbol consists of a brown edged square inside of which is a brown circular patch on a white background. A skull and the following lettering appears in white on the brown patch: DANGER, TOXIC, CONTAINS (name of substance) AVOID INHALING, SWALLOWING, OR CONTACT WITH THE SKIN. Additional information concerning the identification of compressed-gas cylinders and pipelines containing hazardous substances is contained in MIL-STD-101A and MIL-STD-1247A.

TYPES OF HYDRAULIC LIQUIDS

Many different liquids have been tested for use in hydraulic systems. The liquids that are presently in use include mineral oil, vegetable oil, water, phosphate esters, ethylene glycol compounds, and oil in water. Hydraulic liquids are usually classified according to their type of base. The three most common types of hydraulic liquids are water base, petroleum base, and synthetic base.

Water Base Liquids

Water was used as a fluid medium in the first hydraulic systems. It is still suitable for certain large commercial hydraulic installations that require high pressures and low operating speeds, but it does not meet all the requirements for general hydraulic equipment use. As a hydraulic liquid, water presents many problems, such as rust and corrosion, ineffective lubrication, temperature variations, and the hazard of foreign matter in the water itself which might cause an abrasive action on the smooth interior surfaces of the system components. All of these act as factors detrimental to the operating efficiency and long service life of the equipment.

Water has ideal fire resistance. When water is used as a hydraulic liquid, it is usually combined with certain oils, ethylene glycol, and other substances. When combined with oil, the combination is fire resistant until the water evaporates. Then the oil may burn. Other combinations can eliminate ignition problems but may have mechanical or economic limitations. During the early 1950's, the Navy used Hydrolube, a mixture of water and polyethylene glycol (antifreeze compound) in approximately 80 percent of their aircraft. This liquid contained 35 to 40 percent water together with polyethylene glycol, rust inhibitors, thickeners, and lubricating agents. After a few years of use, problems were encountered with thin film corrosion in the aircraft systems using Hydrolube, resulting in the Navy discontinuing its use in aircraft systems. Water base liquids are used by the Navy in the catapult systems on aircraft carriers. This was approved following explosions attributed to petroleum base liquids.

Petroleum Base Liquids

One of the first oils used as a hydraulic liquid was a petroleum base automotive brake fluid. Its use was limited due to the natural rubber seals and packings in use not being compatible with petroleum base oils. As a result, a vegetable base oil containing 50 percent castor oil and 50 percent alcohol was used in some applications. This solved the problems with seals and packings, as natural rubber is compatible with vegetable base oils. However, this liquid was unsatisfactory due to oxidation of the castor oil. Also, liquid is an excellent conductor of electricity, resulting in a high degree of electrolysis (the chemical disintegration of a substance accomplished by an electric current passing through it). Vegetable base liquids also have a very poor temperature stability.

12929
12930

During the middle 1930's, a light petroleum base oil was developed and, when used with asbestos seals, proved quite successful. By the late 1930's, advancement in packing materials, such as synthetic rubber seals, permitted extensive use of petroleum base liquids in hydraulic systems. As a result, a petroleum base oil was developed about 1940 that proved very satisfactory and, with certain refinements, is in use today. This liquid was improved through the use of a number of additives, such as oxidation and corrosion inhibitors, viscosity index improvers, pour depressants, etc. These additives not only permit liquid operation at greater temperature extremes, but add to their lubricating qualities and life characteristics.

Petroleum base liquids are the most widely used media for hydraulic systems. Certain petroleum base oils are used in a number of different applications. For example, MIL-H-5606A is the specification number of the petroleum base hydraulic oil presently used in most Navy aircraft hydraulic systems. Another example is MIL-F-1711 which is the specification number of the petroleum base oil generally approved for ordnance equipment, except guided missiles. Many special petroleum base oils are required for specific applications.

Synthetic Base Liquids

Petroleum base oils contain most of the desired properties required of a hydraulic liquid. However, they are flammable under normal conditions and can become explosively dangerous when subjected to high pressures and a source of flame or high temperatures. Water base liquids are fire resistant, but do not have the high lubricity of petroleum base oils. Some water base liquids cause corrosion of components in the hydraulic system.

In recent years, nonflammable synthetic liquids have been developed for use in hydraulic systems where fire hazards exist. A synthetic material is a complex chemical compound that has been artifically formed by the combining of two or more simpler compounds or elements. Some of the synthetic liquids currently used as a hydraulic medium are chemically described as phosphate esters, chlorinated biphenyls, or blends of each. Certain synthetic liquids have been found to attack packings used in hydraulic systems; therefore, special packings are normally required when these fluids are used.

CONTAMINATION

Experience has shown that trouble in a hydraulic system is inevitable whenever the liquid is allowed to become contaminated. The nature of the trouble—whether a simple malfunction, or the complete destruction of a component—depends to some extent on the type of contaminant.

Classes of Contamination

The two general contamination classes can be distinguished as follows:

1. Abrasives, including such particles as core sand, weld spatter, machining chips, and rust.
2. Nonabrasives, including those resulting from oil oxidation, and soft particles worn or shredded from seals and other organic components.

The mechanics of the destructive action by abrasive contaminants is clear. When the size of the particles circulating in the hydraulic system is greater than the clearance between moving parts, the clearance openings act as filters and retain such particles. Hydraulic pressure then embeds these particles into the softer materials, and the reciprocating or rotating motion of component parts develop scratches on finely finished surfaces. Such scratches result in internal component leakage and decreased efficiency.

Oil-oxidation products, usually called sludge, have no abrasive properties. Nevertheless, sludge may prevent proper functioning of a hydraulic system by clogging valves, orifices, and filters. Frequent changing of hydraulic system liquid is not a satisfactory solution to the contamination problem. Abrasive particles contained in the system are not usually flushed out, and new particles are continually created as friction products. Furthermore, every minute remnant of sludge acts as an effective catalyst to speed up oxidation of the fresh fluid. (A catalyst is a substance which, when added to another substance, speeds up or slows down chemical reaction, but is itself unchanged at the end of the reaction.)

12930

Origin of Contaminants

The origin of contaminants in hydraulic systems can be traced to four major areas as follows:

1. Particles originally contained in the system. These particles originate during fabrication of welded system components, especially in reservoirs and pipe assemblies. The presence is minimized by proper design. For example, seam-welded overlapping joints are preferred, and arc welding of open sections is usually avoided. Hidden passages in valve bodies, inaccessible to sand blasting, are the main source of introduction of core sand. Even the most carefully designed and cleaned casting will almost invariably free some sand particles under the action of hydraulic pressure. Rubber hose assemblies always contain some loose particles, most of which can be removed by flushing, while others withstand cleaning and are freed later by the action of hydraulic pressure.

Particles of lint from cleaning rags can cause abrasive damage in hydraulic systems, especially to closely fitted moving parts. In addition, lint in a hydraulic system packs easily into clearances between packings and contacting surfaces, leading to component leakage and decreased efficiency. Lint also helps clog filters prematurely. Rust or corrosion initially present in a hydraulic system can usually be traced to improper storage of materials and component parts. Particles can range in size from large flakes to abrasives of microscopic dimensions. Proper preservation of stored parts is helpful in eliminating corrosion.

2. Particles introduced from outside forces. Particles can be introduced into hydraulic systems at points where either the liquid or certain working parts of the system (e.g., piston rods) are at least in temporary contact with the atmosphere. The most common danger areas are at the refill and breather openings and at cylinder rod packings. Contamination arising from carelessness during servicing operations is minimized by the use of filters in the system fill lines and finger strainers in the filter adapters of hydraulic reservoirs. Hydraulic cylinder piston rods incorporate wiper rings and dust seals to prevent the dust that settles on the piston rod during its outward stroke from being drawn into the system when the piston rod retracts.

3. Particles created within the system during operation. Contaminants created during system operation are of two general types—mechanical and chemical. Particles of a mechanical nature are formed by wearing of parts in frictional contact, such as pumps, cylinders, and packing gland components. These wear particles can vary from large chunks of packings down to steel shavings of microscopic dimensions which are beyond the retention potential of system filters.

The chief source of chemical contaminants in hydraulic liquid is oxidation. These contaminants are formed under high pressure and temperatures, and are promoted by the catalytic action of water and air and of metals like copper or iron oxides. Oil-oxidation products appear initially as organic acids, asphaltines, gums, and varnishes—sometimes combined with dust particles as sludge. Liquid soluble oxidation products tend to increase liquid viscosity, while insoluble types form sediments and precipitates, especially on colder elements such as heat exchanger coils.

Liquids containing antioxidants have little tendency to form gums under normal operating conditions. However, as the temperature increases, resistance to oxidation diminishes. Hydraulic liquids which have been subjected to excessively high temperatures (above 250° F) will break down in substance, leaving minute particles of asphaltine suspended in the liquids. The liquid changes to brown in color and is referred to as decomposed liquid. This explains the importance of keeping the hydraulic liquid temperature below specified levels.

The second contaminant producing chemical action in hydraulic liquids is one which permits these liquids to establish a tendency to react with certain types of rubber, causing structural changes in the rubber, turning it brittle, and finally causing its complete disintegration. For this reason, the compatibility of system liquid with seals and hose material is a very important factor.

4. Particles introduced by foreign liquids. One of the most common foreign-fluid contaminants is water, especially in hydraulic systems which require petroleum base oils. Water, which enters even the most carefully designed systems by condensation of atmospheric moisture, normally settles to the reservoir bottom. Oil movement in the reservoir disperses the water into fine droplets, and agitation of the liquid in the pump and in high speed passages forms an oil-water-air emulsion. Such an emulsion normally

separates out during the rest period in the system reservoir; but when fine dust and corrosion particles are present, the emulsion is catalyzed by high pressures into sludge. The damaging action of sludge explains the need for effective filtration, as well as the need for water separating qualities in hydraulic liquids.

Contamination Control

Filters (discussed in chapter 6) provides adequate control of the contamination problem during all normal hydraulic system operations. Control of the size and amount of contamination entering the system from any other source must be the responsibility of the personnel who service and maintain the equipment. Therefore, precautions must be taken to insure that contamination is held to a minimum during maintenance repair and service operations. Should the system become excessively contaminated, the filter element should be removed and cleaned or replaced.

As an aid to exercising contamination control, the following maintenance and servicing procedures should be adhered to at all times:

1. Maintain all tools and the work area (workbenches and test equipment) in a clean, dirt-free condition.

2. A suitable container should always be provided to receive the hydraulic liquid which is spilled during component removal or disassembly procedures.

NOTE: The reuse of drained hydraulic liquid is prohibited in some hydraulic systems; for example, aircraft hydraulic systems. In some large capacity systems the reuse of liquid is permitted. When liquid is drained from the latter systems, it must be stored in a clean and suitable container. This liquid must be strained and/or filtered as it is returned to the system reservoir.

3. Before disconnecting hydraulic lines or fittings, clean the affected area with drycleaning solvent.

4. All hydraulic lines and fittings should be capped or plugged immediately after disconnecting.

5. Before assembly of any hydraulic components, wash all parts in an approved drycleaning solvent.

6. After cleaning parts in drycleaning solution, dry the parts thoroughly and lubricate with the recommended preservative or hydraulic liquid before assembly.

NOTE: Use only clean, lint-free cloths to wipe or dry component parts.

7. All seals and gaskets should be replaced during the reassembly procedure.

8. All parts should be connected with care to avoid stripping metal slivers from threaded areas. All fittings and lines should be installed and torqued in accordance with applicable technical instructions.

9. All hydraulic servicing equipment should be kept clean and in good operating condition.

Contamination Checks

FLUID SAMPLING.—Whenever it is suspected that a hydraulic system has become excessively contaminated, or the system has been operated at temperatures in excess of the specified maximum, a check of the system should be made. The filters in most hydraulic systems are designed to remove most foreign particles that are visible to the naked eye. Hydraulic liquid which appears clean to the naked eye may be contaminated to the point that it is unfit for use.

Thus, visual inspection of the hydraulic liquid does not determine the total amount of contamination in the system. Large particles of impurities in the hydraulic system are indications that one or more components in the system are being subjected to excessive wear. Isolating the defective component requires a systematic process of elimination. Liquid returned to the reservoir may contain impurities from any part of the system. In order to determine which component is defective, liquid samples should be taken from the reservoir and various other locations in the system.

Liquid samples should be taken in accordance with the instructions contained in the applicable technical publication for the particular hydraulic system and the contamination test kit. Some hydraulic systems are provided with permanently installed bleed valves for taking liquid samples; while on other systems, lines must be disconnected to provide a place to take a sample. In either case, while the liquid is being taken, a small amount of pressure should be applied to the system. This insures that the liquid will flow out of the sampling point and thus prevent dirt from entering the hydraulic system. Hypodermic syringes are provided with some contamination test kits for the purpose of taking samples.

CONTAMINATION TESTING.—Various test procedures are recommended to determine the contamination level in hydraulic liquids. The filter patch test provides a reasonable idea of the condition of the fluid. This test consists

1298251

basically of filtration of a sample of hydraulic system liquid through a special filter paper. This filter paper darkens in degree in relation to the amount of contamination present in the sample, and is compared to a series of standardized filter disks which, by degree of darkening, indicate the various contamination levels. The equipment provided with one type of contamination test kit is illustrated in figure 3-2.

When using this liquid contamination test kit, the liquid samples should be poured through the filter disk (shown in fig. 3-2), and the test filter patches should be compared with the test patches supplied with the test kit. A microscope is provided with the more expensive test kits for the purpose of making this comparison. Figure 3-3 shows test patches similar to those supplied with the testing kit.

To check liquid for decomposition, pour new hydraulic liquid into a sample bottle of the same size and color as the bottle containing the liquid to be checked. Visually compare the color of the two bottles. Liquid which is decomposed will be darker in color.

At the same time the contamination check is made, it may be necessary to make a chemical test. This test consists of a viscosity check, a moisture check, and a flashpoint check. However, since special equipment is required for these checks, the liquid samples must be sent to a laboratory, where a technician will perform the test.

System Flushing

Whenever a contamination check indicates impurities in the system or indicates

Figure 3-2.—Liquid contamination test kit.

129638

FILTER BOWL SAMPLE

1. Discoloration as dark as or darker than reference disk.
2. More than 2 metal chips larger than 0.01 inch in diameter. (About size of sharp pencil dot.)
3. More than 25 very fine but visible metal particles.

DOWNSTREAM SAMPLE

1. Discoloration as dark as or darker than reference disk.
2. More than 1 metal chip larger than 0.01 inch in diameter. (About size of sharp pencil dot.)
3. More than 10 very fine but visible metal particles.

Figure 3-3.—Hydraulic liquid contamination test patches.

decomposition of the hydraulic liquid, the hydraulic system must be flushed.

NOTE: The presence of foreign particles in the hydraulic system indicates a possible component malfunction, which should be corrected prior to flushing the system.

A contaminated hydraulic system should be flushed in accordance with current applicable technical instructions. Flushing procedures are normally recommended by the manufacturer and approved by the Navy. The procedure varies with different hydraulic systems. The following procedures for flushing hydraulic power-transmission systems used with naval ordnance are covered in NavOrd OD 3000, Lubrication of Ordnance Equipment.

Drain out as much of the contaminated liquid as possible. Drain valves are provided in some systems for this purpose; while on other systems, lines and fittings must be disconnected at the low points of the system to remove any trapped liquid in the lines and components. Close all the connections and fill the system with the applicable flushing medium. Any of the hydraulic liquids approved for use in power-transmission systems may be used for flushing purposes. In the interest of economy, however, either used or reclaimed liquids should be used for flushing, provided they are clean and free from water and insoluble contaminants and do not contain acid resulting from oxidation of the liquids.

CAUTION: Diesel fuel oil must not be used for flushing hydraulic systems in active service, owing to its poor lubricating qualities and its contaminating effect on the subsequent fill or hydraulic liquid.

While being flushed with an approved hydraulic liquid, power-transmission hydraulic systems can be operated at full load to raise the temperature of the liquid. Immediately following the warming operation, the system should be drained by opening all drain outlets and disconnecting the hydraulic lines to remove as much of the flushing medium as possible. All filter elements, screens, and chambers should be cleaned with new fluid prior to filling the system with the required service liquid.

CAUTION: The system should not be operated while or after draining the liquid.

Power-transmission systems and their interconnected hydraulic controls whose inner surfaces have been inactivated and treated with a corrosion preventive or preservation compound must be flushed to remove the compound. The latest current instructions for flushing and other operations required to reactivate a particular system must be strictly followed to prevent damage.

Some hydraulic systems are flushed by forcing new liquid into the system under pressure, forcing out the contaminated or decomposed liquid.

Hydraulic liquid which has been contaminated by continuous use in hydraulic equipment or has been expended as a flushing medium must not be used again, but should be discarded in accordance with prevailing instructions.

CAUTION: Never permit high-pressure air to be in direct contact with petroleum base liquids in a closed system, because of the danger of ignition. If gas pressure is needed, in a closed system, nitrogen or some other inert gas should be used.

1298651

PNEUMATIC GASES

Gases serve the same purpose in pneumatic systems as liquids serve in hydraulic systems. Therefore, many of the same qualities that are considered when selecting a liquid for a hydraulic system must be considered when selecting a gas for a pneumatic system.

QUALITIES

The ideal fluid medium for a pneumatic system must be a readily available gas that is nonpoisonous, chemically stable, free from any acids that cause corrosion of system components, and nonflammable. It should be a gas that will not support combustion of other elements.

The viscosity of gases is not a critical quality to consider in the selection of a medium for pneumatic systems. However, it should be noted that, unlike liquids, the viscosity of gases increases as the temperature rises and decreases as the temperature decreases.

Gases that have these desired qualities do not have the required lubricating power. Therefore, lubrication of the components of a pneumatic system must be arranged by other means. For example, air compressors have their own lubricating system, and components are either lubricated by external sources or upon installation.

TYPICAL GASES USED

The two most common gases used in pneumatic systems are compressed air and nitrogen.

NOTE: Compressed air is a mixture of all the gases contained in the atmosphere. However, in this course it is referred to as one of the gases used as a fluid medium for pneumatic systems.

Compressed Air

The unlimited supply of air and the ease of compression make compressed air the most widely used fluid for pneumatic systems. Some pneumatic systems contain air compressors as the source of supply, while other systems receive their supply from cylinders which are charged (filled to the required pressure) at a centrally located air compressor. Compressed air has most of the desired characteristics of a gas for pneumatic systems. It is nonpoisonous and nonflammable but does contain gases, such as oxygen, which support combustion. Changes in temperature will cause condensation of moisture in the lines; and if the weather becomes extremely cold, this condensation will freeze and make the system inoperative.

Nitrogen

For all practical purposes, nitrogen is considered to be an inert gas. (Inert is defined as chemically inactive; not combining with other chemicals.) It is not completely inert like helium or argon, for there are many nitrogen compounds, such as nitrate used in fertilizers and explosives. However, nitrogen is very slow to combine chemically with other elements under normal conditions. Nitrogen, as a gas, supports no fires, no living things, and causes no rust or decay of most of the things with which it comes in contact. Due to these qualities, its use is preferred over compressed air in many pneumatic systems, especially aircraft and missile systems.

Nitrogen is obtained by the fractional distillation of air. On some ships, particularly aircraft carriers, nitrogen is obtained as a byproduct of the oxygen plant. The nitrogen is compressed into cylinders which are used to fill the pneumatic system to the required pressure.

A combination of nitrogen and compressed air is used in some pneumatic systems. Compressed nitrogen is supplied from cylinders, while a compressor provides compressed air to replenish any expended nitrogen and maintain the pneumatic system at the required pressure.

POTENTIAL HAZARDS

All compressed gases are hazardous. Compressed air and nitrogen are neither poisonous nor flammable, but should not be handled carelessly. Some pneumatic systems operate at pressures exceeding 3,000 psi. Lines and fittings have exploded, injuring personnel and property. Literally thousands of careless men have blown dust or harmful specks into their eyes by the careless handling of compressed air outlets.

Nitrogen gas will not support life, and when released in a confined space will cause asphyxia (the loss of consciousness as a result of too little oxygen and too much carbon dioxide in the blood). Because compressed air and nitrogen seem so safe in comparison with other gases, do not let overconfidence lead to personal injury.

12935 8C6S1

CONTAMINATION CONTROL

Pneumatic systems should be purged periodically to remove contamination, moisture, and oil from the components and lines. Purging of the pneumatic system is accomplished by pressurizing the system and removing plumbing from various components throughout the system. Removal of the pressurized lines will cause a high rate of airflow through the system. This airflow will cause the foreign matter to be exhausted from the system.

NOTE: If an excessive amount of foreign matter, particularly oil, is exhausted from any one system, the lines and components should be removed and cleaned or replaced.

Upon the completion of pneumatic system purging and after reconnecting all the system components, the system drain valves should be opened to exhaust any moisture or impurities which may have accumulated. After all drain valves are closed, the system should be serviced with the approved gas, usually nitrogen or compressed air. The system should then be given a thorough operational check and an inspection for leaks and security.

History has indicated that the development of fluid power and its mechanical equipment goes hand in hand with the development of specific fluids for each intended application. Past breakthroughs in high-temperature fluids have shown that, when future equipment requires fluid power, satisfactory systems and fluids will be available. For example, hot gas fluid power systems are under study and development for use in space vehicles. The hot gases are obtained by bleeding off the main rocket engine or using a solid or liquid propellent gas generator.

5. Relation of Age of Seedlings to Susceptibility to Pythium Damping-Off

OBJECTIVE: To demonstrate that seedlings become more resistant to *Pythium debaryanum* with age.

MATERIALS: A pathogenic isolate of *P. debaryanum*; potato-dextrose broth; 15 sterile 4 or 6 in. pots; enough sterile white quartz sand to fill pots to within 1 inch of top; about 10 sq. ft. of greenhouse space or lighted laboratory space (24°C); about 1500 fungus-free seeds of alfalfa, sweet clover, red clover, or Ladino white clover (seed produced in the more arid regions of western U. S. is best for this purpose; it is most likely to be free of infection); and a small volume of half-strength Hoagland's solution.

PROCEDURES: Grow *P. debaryanum* in potato-dextrose broth in eight 4-liter Erlenmeyer flasks (1200 ml of broth/flask) on shaker for 7 days. Inoculum will develop as small mycelial balls which should be separated from the broth and washed with sterile water before using. The pathogen may be increased on 10 PDA plates for 5 days and the mycelial mats (with agar) broken up. Five sterile agar plates should be included for controls.

Surface disinfect seed in 95% ethyl alcohol and 1% solution of sodium hydrochlorite, dry seed, and count out 15 lots of 100 seeds each. Sow 3 pots with 100 seeds each on each of 5 seedling dates so seedlings will be 6, 3, 2, 1, and zero days old at time of inoculation. Cover seeds with 0.25 in. of sand and add sterile water until all sand in pot is wet. Add inoculum to 2 of the 3 pots of each age group at the rate of 1 heaping tsp/pot. The third pot of each group is the control. Inoculum may be added to surface of sand and washed in with sterile water. Keep sand moist at all times. Sterile water may be used until the seedlings emerge; after emergence, Hoagland's nutrient solution should be used. Pots should have holes in bottoms for drainage.

Compare total emergence, amount of postemergence damping-off, and

CHAPTER 4

BASIC SYSTEMS AND CIRCUIT DIAGRAMS

As with most technical skills, a knowledge of the basic components, systems, and circuits is a prerequisite for understanding and being able to troubleshoot and maintain fluid power equipment. A knowledge of the fundamentals of fluid power requires that the individual begin with the basic skills and progress to the more complex skills. This will require a high proficiency in studying, understanding, and analyzing the basic systems and the circuits which comprise these systems.

COMPONENTS OF A BASIC FLUID SYSTEM

The basic components of a fluid power system are essentially the same, regardless of whether the system employs a hydraulic or pneumatic medium. There are five basic components used in a system. These basic components are as follows:

1. Reservoir.
2. Pump or compressor.
3. Tubing or piping (circulatory system).
4. Control valve or selector valve.
5. Actuating unit.

The primary purpose of a RESERVOIR is to provide storage space for the fluid used in the system. A well designed reservoir can also be used as a heat exchanger to control the temperature of the fluid and may also be used as a place to filter and clean the fluid. Reservoirs are discussed in detail in chapter 6 of this course.

The primary purpose of a PUMP OR COMPRESSOR is to move fluid from one point to another in a fluid system. To do this, the pump or compressor must convert mechanical energy into fluid energy. The basic principles on which a pump or compressor operate are slightly different. Therefore, for more details on pumps and compressors consult chapter 7 of this course.

The CIRCULATORY SYSTEM (TUBING OR PIPING) is the medium for transmitting fluid from one component to another. This is normally accomplished by using either tubing, piping, or flexible hose for interconnecting pumps to cylinders, valves to pumps, reservoirs to valves, etc.

Tubing is used in aircraft where weight is a prime factor, and piping is generally used where weight is not a factor. Flexible hose is generally employed in connection with moving parts or where it is necessary to install a line that is subject to considerable vibration. Circulatory systems are discussed in detail in chapter 5 of this course.

The CONTROL VALVE (also referred to as a selector valve) is a device for directing and controlling the flow or pressure of fluids. Various types of valves are used in fluid systems. A few of the more common valves and their applications are discussed in chapter 11 of this course.

The ACTUATING UNIT of a fluid power system is that device which converts the fluid pressure into useful work. Actuators perform the opposite function of hydraulic pumps and compressors in that they convert fluid energy into mechanical energy.

These five components when combined into one unit are the basis for a fluid power system. An example of a basic fluid power system is shown in figure 4-1.

The flow of fluid can be traced readily from the reservoir through the pump to the control valve. With the control valve in the position shown, the flow of fluid created by the pump flows through the valve to the right-hand end of the actuating cylinder. Fluid pressure then forces the piston to the left and at the same time the fluid which is on the left of the piston is forced out, up through the control valve, and back to the reservoir through the return line.

12937 12938

Figure 4-1.—Basic system, hand pump operated.

When the control valve is moved to the position indicated by the dotted lines, the fluid from the pump then flows to the left side of the actuating cylinder, thus reversing the process. Movement of the piston can be stopped at any time simply by moving the control valve to neutral. In this position, all four ports are closed and pressure is trapped in both working lines. This basic system is one from which any system can be derived. Additions may be made to it for the purpose of providing additional sources of power, operating additional cylinders, making operation more automatic, or increasing the reliability; but these additions are all made on the framework of the basic system diagramed in figure 4-1.

COMPONENTS OF A SIMPLE SYSTEM

With the addition of a few simple components, a basic system can be improved into a more workable system. Figure 4-2 shows a basic system with the addition of a power-driven pump and the following essential components: Filter, pressure regulator, accumulator, pressure gage, relief valve, and two check valves. The function of each of these components is explained in the following paragraphs. Construction, operating features, and maintenance of these components are described later in this course.

The FILTER removes foreign particles from the fluid, preventing dust, grit, and other undesirable matter from entering the system.

The purpose of the PRESSURE REGULATOR is to unload or relieve the power-driven pump when the desired pressure in the system is reached. It is therefore often referred to as an unloading valve.

When one of the actuating units is being operated, and pressure in the line between the pump and control valve builds up to the desired point, a valve in the pressure regulator automatically opens and fluid is bypassed back to the reservoir. This bypass line is shown in figure 4-2 leading from the pressure regulator to the return line.

Many fluid power systems do not use a pressure regulator, but have other means of

12938

1. Reservoir.
2. Power pump.
3. Filter.
4. Pressure regulator.
5. Accumulator.
6. Check valves.
7. Hand pump.
8. Pressure gage.
9. Relief valve.
10. Control valve.
11. Actuating unit.

Figure 4-2.—Basic system with addition of power pump.

unloading the pump and maintaining the desired pressure in the system.

The ACCUMULATOR serves a twofold purpose. It serves as a cushion or shock absorber by maintaining an even pressure in the system, and it stores enough fluid under pressure to provide for emergency operation of certain actuating units. It is designed with a compressed-air chamber separated from the fluid by a flexible diaphragm, synthetic rubber bladder, or a movable piston.

The PRESSURE GAGE indicates the amount of pressure in the system.

The RELIEF VALVE is a safety valve installed in the system so that fluid is bypassed through the valve back to the reservoir in case excessive pressure is built up in the system.

CHECK VALVES allow the flow of fluid in one direction only. There are numerous check valves installed at various points in the lines of most fluid power systems. A careful study of figure 4-2 will reveal why the two check valves are necessary in this system. One check valve prevents power pump pressure from entering the hand-pump line; the other prevents hand-pump pressure from being directed to the accumulator.

CIRCUIT DIAGRAMS AND SYMBOLS OF A SIMPLE SYSTEM

A thorough knowledge of symbols and how to read diagrams are basic requirements for understanding fluid power systems. To understand the diagrams of a system, first requires a knowledge of the symbols used in the schematic diagrams.

Many manufacturers use their own symbols to represent the various components in a system. However, the Navy uses two Military Standards in identifying and using symbols in fluid power systems. These two Military Standards are as follows:

1. Military Standard, Mechanical Symbols (Other than Aeronautical, Aerospacecraft, and Spacecraft Use), Part I, MIL-STD-17B-1.

2. Military Standard, Mechanical Symbols for Aeronautical, Aerospacecraft, and Spacecraft Use, Part 2, MIL-STD-17B-2.

Some of the more pertinent symbols used in fluid power systems have been selected from these two standards and are depicted in tables 4-1 and 4-2 of this chapter.

While the symbols illustrated in this chapter are not all encompassing, they do provide a basis for the man working with fluid power systems to build upon. For greater details on the symbols used in fluid power systems, the reader should consult the above mentioned Military Standards. Also, for additional information on symbols and the reading of diagrams, consult Blueprint Reading and Sketching, NavPers 10077-B.

USES OF DIAGRAMS

In order to troubleshoot fluid power systems intelligently, the mechanic or technician must be familiar with the system at hand. He must know the function of each component in the system and have a mental picture of its location in relation to other components in the system. These can best be achieved by studying the diagrams of the system.

There are many types of diagrams; however, those which are the most pertinent to fluid power systems may be divided into two classes. These diagrams are usually referred to as pictorial or schematic diagrams and are provided by the manufacturer to aid the maintenance man in understanding and troubleshooting the equipment. There may be instances where a schematic diagram will be shown as a pictorial diagram, or the diagram may consist of a combination of the two.

A diagram, whether it is a pictorial or schematic diagram, may be defined as a graphic representation of an assembly or system, indicating the various parts and expressing the methods or principles of operation. As a general rule, the various components are indicated by symbols in schematic diagrams, while drawings of the actual components are used in pictorial diagrams.

Pictorial Diagrams

Pictorial diagrams show general location, function, and appearance of parts and assemblies. An example of a pictorial diagram is the installation diagram shown in figure 4-3. This is a diagram of the liquid oxygen system of a Navy aircraft. It shows the location of each of the components within the aircraft on the principal view. Each letter (A, B, C, etc.) on the principal view refers to a detail view located elsewhere on the diagram. Each detail view is an enlarged drawing of a portion of the system, identifying each of the principal components.

Diagrams of this type are invaluable to maintenance personnel in identifying and locating components, and understanding the principle of operation of various systems.

Schematic Diagrams

The primary purpose of a schematic diagram is to enable the maintenance man to trace the flow of fluid, component by component. This type of diagram does not necessarily indicate the physical location of the various components, but does show the relation of each component to other components within the system.

Figure 4-4 is an example of a schematic diagram of a speed brake system used in a current aircraft. This diagram does not indicate the physical location of the individual components within the aircraft, but does locate components with respect to each other within the system. For example, the check valve in figure 4-4 is not necessarily located immediately above the speed brake control valve. The diagram does indicate, however, that the check valve is located in the pressure line and that the pressure line leads into the control valve.

Schematic diagrams of this type are used mainly in troubleshooting. Note that each line (pressure, return, brakes open, and brakes closed) is coded for ease of reading and tracing the flow. Each component is identified by name, and its location within the system can be ascertained by noting which lines lead into and out of the unit.

In tracing the flow of fluid through the system, it can be seen that the first unit in the pressure line is a check valve. The arrow on the valve indicates the direction of flow through the valve. It is obvious that this check valve is located in the pressure line for the purpose of preventing speed brake pressure from dropping when main system pressure drops momentarily, as when another actuating system is operated.

The next unit in the pressure line is the speed brake control valve. It can be seen that the control valve is a four-port unit, being connected to pressure, return, and to each actuating line.

When the control valve is placed in brakes open position, fluid under pressure is ported through the brakes open line to the actuating cylinders, opening the speed brakes. Also in the brakes open line is a blow-back relief valve. It can be seen that the relief valve is also connected to the return line. It is obvious that its purpose is to protect the speed brakes against excessive wind blasts. For example, if the pilot opened the speed brakes at an airspeed greater than that for which the speed brakes are designed, the blow-back relief valve would open, allowing the excess fluid pressure to return to the reservoir. Thus, the speed brakes would be blown back to the closed position.

12945

Figure 4-4.—Example of a schematic diagram (speed brakes).

SIMPLE HYDRAULIC AND PNEUMATIC SYSTEMS

The simple hydraulic and pneumatic systems are in many respects similar. This can be easily seen by studying the simple systems explained in the following paragraphs. The schematic diagrams presented in this section have been deliberately varied so as to acquaint the individual with the various methods of presenting schematic diagrams.

HYDRAULIC JACK

The hydraulic jack is perhaps one of the simplest forms of a fluid power unit. A heavy load weighing several tons may be lifted by an individual by moving the handle of a small device. A small initial force exerted by an individual is transmitted by means of a fluid to a much larger area. This becomes readily understood by studying figure 4-5. The small input piston has an area of 5 square inches and is

12946

general conditions of inoculated and uninoculated seedlings of different ages.

TIME REQUIRED: About 22 days -- 7 days to increase inoculum and establish seedlings + 15 days from inoculation to final observation.

RESULTS: Disease severity decreased as age of plant at time of inoculation increases.

6. Isolating *Phytophthora* spp. From Soil

OBJECTIVE: To isolate *Phytophthora cinnamomi* or certain other *Phytophthora* spp. from soil or from plant tissue.

MATERIALS: Avocado fruits, firm apples, or green or partially ripe watermelons; cork borers; Scotch tape; corn meal agar; petri dishes.

PROCEDURES: Partially embed apple or avocado in soil in the field or in containers and flood with water or thoroughly moisten soil and place in holes bored into apple or watermelon, using a 0.5 in. cork borer. Cover holes with Scotch tape or masking tape and incubate at room temperature for 5-10 days. Transfer any firm brown rot from margin of rotted area to corn meal agar and examine after 4-5 days or transfer thin slices of the firm rot to water in a petri dish and examine in 4-8 days.

TIME REQUIRED: 5-10 days, depending on temperatures.

RESULTS: *P. cinnamomi* will grow from the soil into buried avocado fruits, *P. cinnamomi* will do the same in apples. However, if soil is placed in holes in apples, other species of *Phytophthora* may be isolated. The technique has also been used to isolate *Pythium ultimum* from soil. Watermelons may exude considerable moisture and should be placed in waterproof containers.

Fruit tissue rotted by *P. cinnamomi* will be firm and only moderately discolored. Any soft rot present is usually caused by other organisms. For positive identification, all rot suspected of being caused by *P. cinnamomi* should be checked in corn meal agar. *P. cinnamomi* may be isolated from avocado, pine, and other roots by placing unsterilized root pieces in apples and placing the resulting rot in corn meal agar.

7. Proof of Pathogenicity of *Agrobacterium tumefaciens* in the Crown Gall Disease

OBJECTIVE: To demonstrate Koch's postulates using the crown gall disease caused by *Agrobacterium tumefaciens* as the example.

Proof of pathogenicity of an organism is obtained by following the general rules first outlined by Robert Koch: (1) A specific organism must always be associated with the disease. (2) This organism must be isolated in pure culture from the diseased host. (3) When inoculated into a healthy susceptible host, under favorable conditions, the organism must produce the characteristic symptoms of the disease in the host. (4) The organism must be reisolated from the artificially inoculated host, obtained in pure culture, and identified as that first isolated.

Figure 4-5.—Hydraulic jack.

directly connected to a large cylinder with an output piston having an area of 250 square inches. The top of this piston forms a lift platform.

If a force of 25 pounds is applied to the input piston, it produces a pressure of 5 pounds per square inch in the fluid. This pressure acting on the 250 square inch area of the output piston will make a force of 1,250 pounds available to raise the lift. An input force of 25 pounds has been transformed into a working force of more than half a ton. However, for this to be true requires that the distance traveled by the input piston be 50 times as great as that traveled by the output piston. Thus, for every inch that the input piston moves the output piston will move only one-fiftieth of an inch.

This would be ideal if the output piston needed to move only a short distance. However, in most instances, the output piston would have to be capable of moving a greater distance to serve a practical application. The device shown in figure 4-5 is not capable of moving the output piston farther than that shown. Therefore, some other means must be employed to raise the output piston to a greater height.

The output piston can be raised higher and maintained at this height if valves are installed as shown in figure 4-6. In this illustration the jack is designed so that it may be raised, lowered, or held at a constant height. These results are attained by introducing a number of valves, and also a reserve supply of fluid to be used in the system.

(A)

(B)

Figure 4-6.—Hydraulic jack; (A) Up stroke; (B) downstroke.

As the input piston is raised (fig. 4-6 (A)), valve 1 is closed by the back pressure from the weight on the output piston. At the same time, valve 2 is opened by the head of fluid in the reservoir. This forces fluid into cylinder 1. When the input piston is lowered (fig. 4-6 (B)), a pressure is developed in cylinder 1. When this pressure exceeds the head in the reservoir, it closes valve 2 and when it exceeds the back pressure from the output piston, it opens valve 1, forcing fluid into the pipeline. The pressure from cylinder 1 is thus transmitted into cylinder 2, where it acts to raise the output piston with its attached lift platform. When the input piston is again raised (fig. 4-6 (A)), so that the pressure in cylinder 1 falls below that in cylinder 2, valve 1 will close, preventing return of the fluid and holding the output piston with its attached lift platform at its new level. Thus, by repeated strokes of the input piston, the lift platform can be progressively raised. To lower the lift platform, valve 3 is opened, and the fluid from cylinder 2 is returned to the reservoir.

12947

HYDRAULIC LIFT

The hydraulic lift functions very similar to the hydraulic jack. The basic difference between the two is the media used to transmit the force.

In the hydraulic lift, air pressure applied to the surface of oil in a reservoir is transmitted by the oil to the output piston of the hydraulic lift. (See fig. 4-7.) Using the compressed air as the input piston, the oil as a means of transferring the force, and the lift attached to the output piston, a means is provided for lifting a heavy automobile. When the release valve is opened, the compressed air pressure drops, the oil returns to the reservoir, and the automobile is lowered.

HYDRAULIC BRAKES

The hydraulic brake system used in the automobile is a multiple piston system. A multiple piston system allows forces to be transmitted to two or more pistons in the manner indicated in figure 4-8. Note that the pressure set up by the force applied to the input piston (1) is transmitted undiminished to both output pistons (2 and 3), and that the resultant force on each piston is proportional to its area. The multiplication of the output pistons is the same as that explained in the preceding paragraphs.

A practical application of multiple outlet pistons to distribute forces can be found in the four-wheel hydraulic brake system commonly used on automobiles. (See fig. 4-9.)

When the brake pedal is depressed, the pressure on the brake pedal moves the piston within the master cylinder, forcing the brake fluid from the master cylinder through tubing and flexible hose into the wheel cylinders. The wheel cylinders contain two opposed output pistons, each of which is attached to a brakeshoe fitted inside the brakedrum. Each output

Figure 4-7.—Hydraulic lift.

12948

piston pushes its brakeshoe against the wall of the brakedrums, thus retarding the rotation of the wheel. When pressure on the pedal is released, the springs on the brakeshoes return the wheel cylinder pistons to their released positions. This action forces the brake fluid back through the flexible hose and tubing to the master cylinder. There is also a return spring in each brake cylinder and one at the brake pedal.

Figure 4-8.—Multiple piston.

The force applied to the brake pedal produces a proportional force on each of the output pistons, which in turn apply the brakeshoes frictionally to the turning wheels to retard rotation. If all eight output pistons were of the same size, the force exerted on each brakeshoe would be exactly the same, provided frictional losses from the master cylinder to each wheel were equal. Likewise, if the brakeshoes were identical, each wheel would be equally retarded.

In actual brake designs, it is customary to use a greater piston area for the rear wheels than for the front. This produces a greater braking action at the rear in a constant and predetermined ratio, and helps to keep the vehicle under control when stopping suddenly on slippery pavements.

HAND WATER PUMP

A pump is a mechanism that uses an external source of power to apply force to a fluid. All pumps in open hydraulic systems take advantage of the fact that the earth's atmosphere, a gaseous fluid, exerts a static pressure, the existence of which becomes noticeable whenever a partial vacuum is created.

Figure 4-9.—An automobile brake system.

12949 7
12820

Anybody who drinks through a straw is making use of this phenomenon. By sucking on the straw, a partial vacuum is created. Atmospheric pressure, acting on the fluid in the tumbler, forces enough of it up the straw to dispel the partial vacuum.

In the hand pump shown in figure 4-10, the lever type pump handle is joined to a piston rod with a simple upward-opening check valve (1) in the piston. The downstroke of the piston applies pressure to the water in the pump, opening the check valve (1) and closing another check valve (2) at the base of the pump.

On the up stroke of the piston, pressure is reduced, and a partial vacuum is created in the area between the two valves. When the check valve (1) closes, atmospheric pressure in the well forces water up the pipe. The upward thrust of the water opens the other check valve (2), but is not strong enough to open the first check valve (1) as long as the piston continues to rise. The excess water thus drawn into the pump flows from the spout.

DOORSTOP

A doorstop is a mechanism for reducing the speed of a closing door. Doorstops vary in size, shape, design, media, and the principle used to control the door's movement. Hydraulic doorstops are normally used in controlling heavy doors, while pneumatic doorstops are used for lighter type doors. The most commonly used doorstop consists of a cylinder and piston especially designed to cushion or buffer the quick motions of the closing door.

In a pneumatic doorstop, the cushion or buffer effect is attained by the transmission of the motion to the piston rod, which thereupon forces the piston head against the volume of air within the cylinder. The air is compressed and absorbs most of the motion, while graduated holes in the cylinder permit the air to escape slowly and the piston and door behind it are brought gradually to rest.

In the hydraulic type, a liquid (oil) is used to cushion the motion of the door. Two cylinders are generally interconnected by an orifice

Figure 4-10.—Hand water pump.

12950

through which the liquid is forced as the door is opened or closed. The door can thus close only as rapidly as the liquid can be moved through the orifice.

AIRBRAKES

Airbrakes were developed to enable the driver to apply sufficient braking action to the wheels of high-speed, heavily-loaded vehicles. With modern airbrake systems, the brake pedal is merely a controlling device for the braking force, which is compressed air. On a vehicle that tows trailers provided with airbrakes, an additional hand controller is provided, which may be operated separately or in conjunction with the pedal. Airbrakes are a form of power brakes. Being more powerful than the hydraulic brakes previously described, they must be larger so that the individual brake will have a greater braking area.

In an airbrake system (fig. 4-11), an engine-driven air pump or compressor is used to compress air and force it into a reservoir, where it is stored under pressure and made available for operating the brakes. Air under pressure in the reservoir is released to the brake lines by an air valve operated by the brake pedal. This released air goes to brake chambers located close to the wheel brakes, which contain a flexible diaphragm and plate. The force of the compressed air admitted to the chamber causes the diaphragm to move the plate, and operates the

Figure 4-11.—Typical airbrake system.

12951

brakeshoes through a mechanical linkage. Considerable force is available for braking since the operating air pressure may be as high as 100 pounds per square inch. All brakes on a vehicle, and on a trailer when one is used, are operated by means of special regulating valves.

AIR-OVER-HYDRAULIC BRAKE SYSTEM

The air-over-hydraulic brake system uses the principle of the hydraulic brake to operate the wheel brake cylinders and produce braking action. However, the hydraulic pressure for the wheel brake cylinders is not supplied from the master cylinder. Instead, there are two circuits. The first leads from the air-hydraulic cylinder and admits air pressure which actuates this cylinder by moving an air piston that is connected to a hydraulic piston. The hydraulic piston then applies the hydraulic pressure that produces the braking action. The air is admitted by the action of valves controlled by the hydraulic pressure from the master cylinder.

An air-over-hydraulic brake system is shown in figure 4-12. Air pressure is supplied by a compressor and stored in reservoirs. The master cylinder is similar to the master cylinders used in hydraulic brakes. Also, the wheel brake cylinders and wheel brake construction are very similar to that used in hydraulic brakes. The essential difference between the straight hydraulic brake system and the air-over-hydraulic brake system lies in the air-hydraulic cylinder. This cylinder consists of three essentials: a large diameter air piston; a small diameter hydraulic piston in tandem with it, both on the same rod; and a set of valves controlled by hydraulic pressure from the master cylinder for admitting air into the air cylinder section of the air-hydraulic cylinder.

The air-hydraulic cylinder embodies an air cylinder and a hydraulic cylinder in tandem, each fitted with a piston with a common piston rod between. The air piston is of greater diameter than the hydraulic piston. This difference in areas of the two pistons gives a resultant hydraulic pressure much greater than the air pressure admitted to the air cylinder. Automatic valves, actuated by fluid pressure from the master cylinder, control the air admitted to the air cylinder. Thus, the fluid pressure in the brake lines is always in a direct ratio to foot pressure on the brake pedal. An air line from the air-hydraulic cylinder leads to a trailer coupling at the rear of the vehicle.

Valve action varies with the amount of brake pedal pressure. When heavy brake pedal pressure is applied by the driver for hard braking, the hydraulic pressure in the master cylinder (which operates the valves) causes greater valve movement, and therefore the valves admit more air pressure into the air-hydraulic cylinder. This higher air pressure causes a stronger braking action. With only a light brake pedal pressure, the valves admit less air pressure into the air-hydraulic cylinder and the braking action is lighter.

12952

Figure 4-12.—Air-hydraulic brake system.

CHAPTER 5

CIRCULATORY SYSTEM COMPONENTS

The components of a fluid power system must be interconnected by lines to convey the fluid throughout the system. These lines—pipes, tubing, and hose—and the necessary fittings make up the circulatory system of fluid power systems.

REQUIREMENTS OF CIRCULATORY SYSTEMS

The proper selection and installation of the lines are of utmost importance in hydraulic or pneumatic systems. An improperly piped system can lead to a serious power loss or harmful fluid contamination. The circulatory system of a fluid power system is designed with several basic requirements in mind. The following is a list of some of the most important requirements which must be considered:

1. The lines must be of sufficient strength to contain the fluid at the desired working pressure and, in addition, must be strong enough to withstand the surges of pressure that may develop in the system during any portion of the operating cycle.
2. The lines must have sufficient strength to support components which may be mounted in or on them.
3. Terminal fittings (flanges, unions, etc.) must be provided at all junctions with parts or components that require removal for repair or replacement.
4. Line supports must be capable of damping shock waves caused by surges of pressure and changes in direction of fluid flow.
5. The lines should have a smooth interior surface to reduce turbulent flow of fluid.
6. The lines must be of the correct size to insure the required flow of fluid during all system operations.
7. After installation, lines must be kept clean by flushing or purging regularly. Any source of contaminant must be eliminated.

TYPES OF CIRCULATORY SYSTEMS

The three most common types of lines used in fluid power systems are pipes, tubing, and flexible hose. They are sometimes referred to as rigid, semirigid, and flexible. A number of factors are considered when selecting the type of circulatory system for a fluid power system. These factors include the type of fluid medium, required pressure of the system, and location of the system. For example, heavy pipe might be used for a large stationary fluid power system, but comparatively lightweight tubing must be used in aircraft and missiles because weight and space are critical factors.

PIPING AND TUBING

In commercial usage, there is no clear distinction between pipe and tubing, since the correct designation for each tubular product is established by the manufacturer. If the manufacturer calls a product pipe, it is pipe; if he calls it tubing, it is tubing.

In the Navy, however, a distinction is made between pipe and tubing. This distinction is based on the way the tubular product is identified as to size.

Sizes

There are three important dimensions of a tubular product—outside diameter (OD), inside diameter (ID), and wall thickness. A tubular product is called tubing if its size is identified by actual measured outside diameter and by actual measured wall thickness. A tubular product is called pipe if its size is identified by a nominal dimension and wall thickness.

In the past, wall thickness of pipe was classified as standard, extra strong, and double extra strong. These designations are still

12954

used to some extent. However, pipe is manufactured in a number of different wall thicknesses and does not always fit into the standard, extra strong, or double extra strong classifications. In recent years, a trend has developed toward the use of scheduled numbers to classify the wall thickness of pipe and pipe fittings. These schedule numbers, established by the American Standards Association, range from 10 to 160 and cover 10 distinct sets of wall thickness. (See table 5-1.) Schedules 40 and 80 are comparable in thickness for most nominal pipe sizes to the standard and extra strong classes, respectively. Schedule 160 covers pipes with the greatest wall thicknesses in this classification, but are slightly thinner than the double extra strong class. The table includes only pipe sizes up through 12-inch nominal size, although larger sizes are available. Schedule 10 is for nominal pipe sizes larger than 12 inches.

A nominal dimension is close to—but not necessarily identical with—an actual measured dimension. As indicated in table 5-1, a pipe with a nominal size of 3 inches has an actual measured outside diameter of 3.500 inches. A pipe with a nominal size of 2 inches has an actual measured outside diameter of 2.375 inches. In the larger size (above 12 inches) the nominal pipe size and the actual measured outside diameter are the same. For example, a pipe with a nominal pipe size of 14 inches

Table 5-1. —Wall thickness schedule designations for pipe.

Nominal size	Pipe OD	Inside diameter									
		Sched. 10	Sched. 20	Sched. 30	Sched. 40	Sched. 60	Sched. 80	Sched. 100	Sched. 120	Sched. 140	Sched. 160
1/8	0.405				0.269		0.215

12	12.750		12.250	12.090	11.934	11.626	11.376	11.064	10.750	10.500	10.126

12955

has an actual measured outside diameter of 14 inches. Nominal dimensions are used in order to simplify the standardization of pipe fittings, pipe taps, and threading dies.

Tubing differs from pipe in its size classification. Tubing is designated by its actual outside diameter. (See table 5-2.) Thus, 5/8-inch tubing has an outside diameter of 5/8 inch. As indicated in the table, tubing is available in a variety of wall thicknesses. The diameter of tubing is often measured and indicated in 16ths. Thus, No. 6 tubing is 6/16 or 3/8 inch, No. 8 tubing is 8/16 or 1/2, etc.

The foregoing is a brief description of the standard ways to identify the size and wall thickness of pipe and tubing. It should be noted, however, that pipe and tubing are sometimes identified in other ways. For example, some tubing is identified by ID rather than by OD and some pipe is identified by nominal pipe size, by OD, by ID, and by actual measured wall thickness.

MATERIALS: A tomato plant (10-11 wk. old) that has been inoculated with A tumefaciens and has young (10-20 day old) gall formations; young potted tomato plants (6-8 wk. old); saturated solution of calcium hypochlorite; saturated solution of sodium thiosulfate; inoculating needles (Dissecting needles may be used) and a platinum loop; several test-tube slants and petri dishes of nutrient agar; test tubes of nutrient broth and sterile water blanks; forceps; scalpel; razor blade; mortar and pestle.

PROCEDURE: (1) Isolation of Agrobacterium tumefaciens: Select galls on an inoculated tomato plant that are still young (10-20 days old). Cut 1 of the galls from the stem of the plant using a sterile scalpel and sterile forceps. Immerse the gall in a vial of saturated calcium hypochlorite for 5 seconds and neutralize immediately in a saturated solution of sodium thiosulfate. Triturate the surface-sterilized gall in 20 ml of sterile distilled water using a sterile mortar and pestle.

Dip a sterile platinum loop in the ground gall suspension and make serial streaks on 2 nutrient agar petri dishes. Incubate these plates (in an inverted position) for 48 hours at 30°C. Check the streak plates for presence of colonies at 24 hr. intervals. Colonies may not be visible until the second or third day, but in 4-5 days convex, pearly lustered colonies 1.5-2 mm in diameter should be visible. Colonies appearing earlier and attaining a diameter of 4-5 mm in 4-5 days can be discarded since they are probably saprophytes. Comparisons should be made with valid cultures of the crown gall bacterium.

With a sterile platinum loop, transfer a portion of a typical colony (small, white, circular, glistening, translucent) from 1 of the petri dishes to nutrient agar slants and nutrient broth tubes.

(2) Observations of colonies isolated from tomato gall: Observations can be made using a hanging-drop preparation, the relief staining technique and the standard Gram staining procedure. Characteristics which should be determined are motility, general morphology, and reaction to Gram's stain (negative or positive).

(3) Inoculation of tomato plants with Agrobacterium tumefaciens: Puncture 2 tomato plants through a stem internode with a sterile inoculating needle and repeat the procedure at another internode. These tomato plants will serve as controls.

Dip a sterile inoculating needle into the bacterial growth on 1 of the nutrient agar slants and inoculate immediately 1 of the tomato plants by puncturing the needle through a stem internode. Repeat this procedure at 2 other internodes and inoculate several other plants in the same manner.

For the next several weeks maintain the inoculated plants under favorable conditions of watering and light at 16° - 24°C. During this period, observe the tomato plants for the development of tumorlike swellings characteristic of crown gall at inoculation points.

(4) Reisolation of the bacterium: While the galls are still young (10-20 days old), repeat procedures described in (1) and (2).

Materials

Pipes and tubing are commonly made from case iron, steel, copper, brass, aluminum, and stainless steel. All of these have their own distinct advantages or disadvantages in certain applications.

Steel pipe and tubing are relatively inexpensive, and are used in many hydraulic and pneumatic systems. Steel is used because of its strength, its suitability for bending and flanging, and its adaptability to high pressures and temperatures. Its chief disadvantage is its comparatively low resistance to corrosion.

Copper piping and tubing are sometimes used for fluid power circulatory systems. Copper has high resistance to corrosion and is easily drawn or bent. It is unsatisfactory for high temperatures and has a tendency to harden and break due to stress and vibration.

Since weight elimination is vital in aircraft design, the majority of circulatory systems in naval aircraft fluid power systems contain aluminum alloy tubing. Two aluminum alloys are in common use—alloy 5052 may be used for lines carrying pressures up to 1,500 psi, and alloy 6061 for pressures up to 3,000 psi. Stainless steel tubing is used in certain parts of many aircraft fluid power systems. As a general rule, exposed lines and lines subject to abrasion or intense heat are made of stainless steel.

Application

The material, the inside diameter, and the wall thickness are the three primary considerations in the selection of lines for the circulatory system of a particular fluid power system. Most of the advantages and disadvantages of the metals used for the manufacture of fluid power lines were covered in the preceding paragraphs.

The inside diameter of a line is important, since it determines the rate of flow that can be passed through the line without loss of power due to excessive friction and heat. Velocity of a given flow is less through a large opening than through a small opening. If the inside diameter of the line is too small for the amount of flow, excessive turbulence and friction heat cause unnecessary power loss and overheated fluid.

The wall thickness, the material used, and the inside diameter determine the bursting pressure of a line or fitting. The greater the wall thickness in relation to the inside diameter and the stronger the metal, the higher the bursting pressure. However, the greater the inside diameter for a given wall thickness, the lower the bursting pressure, because force is the product of area and pressure. Industrial activities recommend that rigid lines should have a bursting pressure which provides a safety factor of at least eight; that is the rated bursting pressure should be at least eight times greater than the maximum working pressure in the system.

The manufacturers of tubing and pipe usually supply charts, graphs, or tables which aid in the selection of the proper lines for fluid power systems. These tables and charts use different methods for deriving the correct sizes of pipe and tubing. Regardless of the method, some provision must be made for correlating the strength of the line in terms of bursting pressure with the inside diameter in terms of flow capacity at recommended velocity.

The units of fluid power systems are designed as compactly as is practicable, in order to keep the connecting lines short. Every section of line should be anchored securely in one or more places so that neither the weight of the line nor the effects of vibration are carried on the joints. The aim should be to minimize stress throughout.

Lines should normally be kept as short and free of bends as possible. However, tubing should not be assembled in a straight line, because a bend tends to eliminate strain by absorbing vibration and compensates for thermal expansion and contraction. Bends are preferred to elbows, because bends cause less of a power loss. A few of the incorrect and correct methods of installing tubing are illustrated in figure 5-1.

Bends are described in terms of the ratio of the radius of the bend to the inside diameter of the tubing or pipe. The ideal bend radius is 2 1/2 to 3 times the inside diameter, as shown in figure 5-2. If the inside diameter of a line is 2 inches, the radius of the bend should be between 5 and 6 inches.

While friction head increases markedly for sharper curves than this, it also tends to increase up to a certain point for gentler curves. The increases in friction in a bend with a radius of more than about 3 pipe diameters result from increased turbulence on the outside edges of the flow. (See glossary.) Particles of fluid must travel a longer distance in making the change

12957 82851

Figure 5-1.—Correct and incorrect methods of installing tubing.

Figure 5-2.—Ideal bend radious.

in direction. When the radius of the bend is less than about 2 1/2 pipe diameters, the increased pressure loss is due to the abrupt change in direction of flow, especially for particles on the inside edge of the flow.

Cutting and bending of pipe and tubing are covered in Basic Handtools, NavPers 10085-A, in other applicable Navy Training Courses, and in applicable technical publications.

FLEXIBLE HOSE

Hose is used in fluid power systems where there is a necessity for flexibility, such as connections to units that move while in operation, or to units attached to a hinged portion of the equipment. It is also used in locations that are subjected to severe vibration. Flexible hose is usually used to connect the pump to the system. The vibration that is set up by an operating pump would ultimately cause rigid tubing to fail.

Sizes

Flexible hose is designated by a dash number, according to its size. The dash number is stenciled on the side of the hose and will indicate the size which refers to the equivalent tubing size. It does not denote the inside or outside diameter of the hose. For example, a hose with -8 stenciled on it is used with No. 8 tubing. The No. 8 tubing has an outside diameter of 1/2 inch (8/16). The inside diameter of the hose will not be 1/2 inch; it will be slightly smaller to allow for wall thickness. The actual inside diameter of both the hose and tubing is the same. As long as the dash number of the hose corresponds with the number of the tubing, the proper size is being used.

The following is a complete breakdown for a hose designation:

This information and the date of manufacture are usually stenciled on the outside of the hose. On some of the newer type flexible hose, the information is placed on a metal tag and attached to the hose.

12958

Materials

RUBBER.—Flexible rubber hose consists of a seamless synthetic rubber tube covered with layers of cotton braid and wire braid, and an outer layer of rubber-impregnated cotton braid. The inner tube is designed to withstand the attack of the material which pass through it. The braid, which may consist of several layers, is the determining factor in the strength of the hose. The cover is designed to withstand external abuse.

TEFLON.—Teflon hose is a flexible hose designed to meet the requirements of higher operating pressures and temperatures in present fluid power systems. Teflon hose consists of a chemical resin, which is processed and extruded into tube shape to a desired size. It is covered with stainless steel wire which is braided over the tube for strength and protection.

Teflon hose is unaffected by all fluids presently used in fluid power systems. It is inert to acids, both concentrated and diluted. Certain Teflon hose may be used in systems where operating temperatures range from -100° F to + 500° F. Teflon is nonflammable; however, where the possibility of open flame exists, a special asbestos fire sleeve should be used.

Teflon hose will not absorb moisture. This, together with its chemical inertness and anti-adhesive characteristics, make it ideal for missile fluid power systems where noncontamination and cleanliness are so essential.

Application

Flexible hose is provided in four pressure ranges. Low-pressure hose is used in low-pressure fluid power systems and for exhaust lines of high-pressure systems. Medium-pressure hose is used in fluid power systems with pressures up to 1,200 psi; high-pressure hose is used in systems with pressures up to 3,000 psi; and extra-high-pressure hose in systems with pressures up to 5,000 psi. High-pressure and extra-high-pressure hose are available only in complete assemblies with factory installed end fittings. Medium-pressure and low-pressure hose are available in bulk and are usually fabricated locally. The fabrication of hose assemblies is covered in applicable Navy Training Courses and technical publications.

Flexible hose must not be twisted on installation, since this reduces the life of the hose considerably and may cause the fittings to loosen as well. Twisting of the hose can be determined from the identification stripe running along its length. This stripe should not tend to spiral around the hose. (See fig. 5-3.)

Flexible hose should be protected from chafing by wrapping lightly with tape, but only where necessary.

The minimum bend radius for flexible hose varies according to size and construction of the hose, and the pressure under which the system will operate. Current applicable technical publications contain tables and graphs showing minimum bend radii for the different types of installations. Bends which are too sharp will reduce the bursting pressure of flexible hose considerably below its rated value.

Flexible hose should be installed so that it will be subjected to a minimum of flexing during operation. Support clamps are not necessary with short installations, but with hose of

Figure 5-3.—Correct and incorrect installation of flexible hose.

12959

considerable length (48 inches for example), clamps should be placed not more than 24 inches apart. Closer supports are desirable and in some cases needed.

A flexible hose must never be stretched tight between two fittings. About 5 to 8 percent of the total length must be allowed as slack to provide freedom of movement under pressure. When under pressure, flexible hose contracts in length and expands in diameter. Examples of correct and incorrect installations of flexible hose are illustrated in figure 5-3.

All Teflon hose should be handled carefully during removal or installation. Sharp or excessive bending will kink or damage the hose. Teflon flexible hose tends to form itself to the installed position in the circulatory system. Some Teflon hose is performed during fabrication. Upon removal of such hose, the preformed section must be handled carefully to prevent straightening or kinking.

TYPES OF CONNECTORS

Fittings are used to connect the units of a fluid power system, including individual sections of the circulatory system. There are many different types of connectors provided for fluid power systems. The type of connectors required for a system depends on the type of circulatory system (pipe, tubing, or flexible hose), the fluid medium, and the maximum operating pressure of the system. Some of the most common types of connectors are described in the following paragraphs.

Threaded Connectors

Threaded connectors are used in some low-pressure fluid power systems. In Navy systems they are usually made of steel, copper, or brass, and in a variety of designs, some of which are illustrated in figure 5-4.

Threaded connectors are made with standard female threading cut on the inside surface. The end of the pipe is threaded with outside (male) threads for connecting. Standard pipe threads are tapered slightly to insure tight connections. The amount of taper is approximately three-fourths of an inch in diameter per foot of thread. (See fig 5-5.)

Metal is removed when a pipe is threaded, thinning the pipe and exposing new and rough surfaces for chemical action. Corrosion agents work more quickly at such points than elsewhere. If pipes are assembled with no protective compound on the threads, corrosion sets in at once and the two sections stick together so that the threads seize when disassembly is attempted. The result is damaged threads and pipes.

Figure 5-4.—Threaded pipe connectors.

Figure 5-5.—Standard taper for pipe threads.

To prevent seizing, a suitable pipe thread compound is sometimes applied to the threads as illustrated in figure 5-6. The two end threads are kept free of compound so that it will not contaminate the fluid. Pipe compound, when improperly applied, may get inside the lines and harm pumps and control equipment. This has been such a problem that many manufacturers forbid the use of any compound when fabricating the piping for fluid power systems.

Flanged Connectors

Bolted flange joints (fig. 5-7) are suitable for most pressures now in use. The flanges are attached to the piping by welding, brazing, tapered threads (for some low-pressure piping), or rolling and bending into recesses. Those illustrated are the most common types of flange joints used. The same types of standard fitting shapes (tee, cross, elbow, etc.) are manufactured for flange joints, such as the threaded fittings illustrated in figure 5-4.

Figure 5-6.—Application of protective compound to pipe threads.

Figure 5-7.—Four types of bolted flange connectors.

Welded Connectors

The subassemblies of some circulatory systems are connected by welded joints, especially in high-pressure piping systems. The welding is accomplished according to standard specifications which define the materials and techniques. There are three general classes of welded joints—butt-weld, fillet-weld, and socket-weld (fig. 5-8).

Brazed Connectors

Silver-brazed connectors (fig. 5-9) are commonly used for joining nonferrous (copper, brass, etc.) piping in the pressure and temperature range where their use is practical. These practical factors limit the use of this type of connector to lines not exceeding 425° F; for cold lines, these fittings may be used for pressures up to 3,000 psi. The alloy is melted

Figure 5-8.—Various types of welded joints.

1296109

Figure 5-9.—Silver-brazed connectors.

by heating the joint with an oxyacetylene torch. This causes the alloy insert to melt and fill the few thousandths of an inch annular space between the pipe and the fitting.

A fitting which has been removed from a piping system can be rebrazed into a system, as in most circumstances sufficient alloy remains in the insert groove for a second joint. New alloy inserts may be obtained for fittings which do not have sufficient alloy remaining in the insert for making a new joint.

Figure 5-10.—Flared-tube connector.

Flared Connectors

Flared connectors are commonly used in circulatory systems consisting of lines made of tubing. These connectors provide safe, strong, dependable connections without the necessity of threading, welding, or soldering the tubing. The connector consists of a fitting, a sleeve, and a nut, as illustrated in figure 5-10.

Fittings are made of steel, aluminum alloy, or bronze. The fittings should be of material similar to that of the sleeve, nut, and tubing. For example, use steel connectors with steel tubing and aluminum alloy connectors with aluminum alloy tubing. Fittings are made in unions, 45-degree and 90-degree elbows, tees, and various other shapes. Figure 5-11 illustrates some of the most common fittings used with flared connectors. Tees, crosses, and elbows are self-explanatory. Universal and bulkhead fittings can be mounted solidly with one outlet of the fitting through a bulkhead and the other outlet(s) positioned at any angle. Universal denotes the fact that the fitting can assume the angle required for the specific installation. Bulkhead denotes that it is long enough to pass through a bulkhead. Figure 5-12 illustrates a universal bulkhead-mounted fitting.

As indicated in figure 5-11, fittings are available in many different thread combinations. Unions have tube connections on each end; elbows have tube connections on one end and a male pipe thread, female pipe thread, or a tube connection on the opposite end. Tees and crosses have several different combinations.

Tubing used with this type of connector must be flared prior to assembly. The nut fits over the sleeve and when tightened, draws the sleeve and tubing flare tightly against the male fitting to form a seal.

12962

Figure 5-11.—Flared-tube fittings.

12963

Figure 5-12.—Universal bulkhead-mounted fitting.

The male fitting has a cone-shaped surface with the same angle as the inside of the flare. The sleeve supports the tube so that vibration does not concentrate at the edge of the flare, and distributes the shearing action over a wider area for added strength. Tube flaring is covered in Basic Handtools, NavPers 10085-A, and other applicable Navy Training Courses.

Correct and incorrect methods of installing flared-tube connectors are illustrated in figure 5-13. Tubing nuts should be tightened with a torque wrench to the value specified in applicable technical publications.

Figure 5-13.—Correct and incorrect methods of tightening flared connectors.

If an aluminum alloy flared connector leaks after tightening to the specified torque, it must not be tightened further. The leaking connector must be disassembled and the fault corrected.

If a steel connector leaks, it may be tightened 1/6 turn beyond the specified torque in an attempt to stop the leakage; then, if unsuccessful, it must be disassembled and repaired.

Some of the causes of leaking flared connectors are as follows:

1. Flare distorted into nut threads.
2. Sleeve cracked.
3. Flare cracked or split.
4. Flare out of round.
5. Flare eccentric to tube OD.
6. Inside of flare rough or scratched.
7. Fitting cone rough or scratched.
8. Threads of fitting or nut dirty, damage, or broken.

Bite Type Connectors

Bite type connectors are commonly referred to as flareless-tube connectors. This type connector eliminates all tube flaring, yet provides a safe, strong, and dependable tube connection. This connector consists of a fitting, a sleeve or ferrule, and nut. (See fig. 5-14.)

Flareless-tube fittings are available in many of the same shape and thread combinations as the flared type fittings illustrated in figure 5-11. An example of a flareless-tube fitting is illustrated in figure 5-15. The fitting has a counterbore shoulder for the end of the tubing to rest against. The angle of the counterbore causes the cutting edge of the sleeve or ferrule to cut into the outside of the tube when the two are assembled together.

The nut presses on the bevel of the sleeve and causes it to clamp tightly to the tube. Resistance to vibration is concentrated at this point rather than at the sleeve cut. When fully tightened, the sleeve or ferrule is bowed slightly at the midsection and acts as a spring. This spring action of the sleeve or ferrule maintains a constant tension between the body and the nut and thus prevents the nut from loosening.

Prior to the installation of a new flareless-tube connector, the tubing must be square, concentric, and free of burrs. For the connection to be effective, the cutting edge of the sleeve or ferrule must bite into the periphery of the tube. This is accomplished by presetting the sleeve or ferrule on the tube using a presetting tool which has the same dimensions as the

12964
15863

Figure 5-14.—Flareless-tube connector.

Figure 5-15.—Flareless-tube fitting.

fitting body, and which can be obtained from the fitting manufacturer. If a presetting tool is not available, a suitable male-thread fitting may be used. Steel fittings are preferred for this operation. If an aluminum fitting is used as a preset tool it should not be reused in the system.

Applicable Navy Training Courses, technical publications, or specifications may be consulted for the proper procedure to be followed for presetting flareless-tube connectors.

After presetting, the connector is disassembled for inspection. If the sleeve or ferrule is satisfactorily installed, the connector is ready for final assembly in the system. When making the final assembly in the system, the following installation procedure should be followed.

1. Lubricate all threads with a liquid that is compatible with the fluid that is to be used in the system.

2. Place the tube assembly in position and check for alignment.

3. Tighten the nut by hand until the increase in resistance to turning is encountered. This indicates that the sleeve pilot has contacted the fitting.

4. With a wrench, turn the nut 1/6 turn (one hex side). Use a wrench on the hex of the fitting to prevent it from turning while tightening the nut.

CAUTION: Overtightening will yield and damage the fitting. If the connection leaks after tightening to the foregoing instructions, it may be tightened an additional 1/6 turn. If this does not stop leakage, the connector must be disassembled and repaired. Always remember, DO NOT OVERTIGHTEN FLARELESS-TUBE CONNECTORS.

Connectors for Flexible Hose

Most of the flexible hose used in Navy fluid power systems must be drawn from supply as an assembly and is equipped with end fittings that are applicable to the particular system. The end fittings most commonly used on flexible hose used in fluid power systems are either for the flared or flareless type connectors. Hose is also available with fittings adaptable to flange type connectors. Examples of end fittings for flexible hose are illustrated in figure 5-16.

Quick-Disconnect Couplings

Quick-disconnect couplings of the self-sealing type are used at various points in many fluid power systems. These couplings are installed at locations where frequent uncoupling of the lines is required for inspection, test, and maintenance.

Quick-disconnect couplings provide a means of quickly disconnecting a line without the loss of fluid from the system or entrance of foreign matter into the system. Several types of quick-disconnect couplings have been designed for use in fluid power systems. Figure 5-17 illustrates a coupling that is used with portable pneumatic tools. The male section is connected to the tool or to the line leading from the tool. The female section, which contains the shutoff valve, is installed in the pneumatic line leading from the power source. These connectors can be separated or connected by very little effort on the part of the operator.

The most common quick-disconnect coupling for hydraulic systems consists of two parts,

held together by a union nut. Each part contains a valve which is held open when the coupling is connected, allowing fluid to flow in either direction through the coupling. When the coupling is disconnected, a spring in each part closes the valve, preventing the loss of fluid and entrance of foreign matter.

The union nut has a quick-lead thread which permits connecting or disconnecting the coupling by turning the nut. The amount the nut must be turned varies with different styles of couplings. For one style, a quarter turn of the union nut locks or unlocks the coupling. For another style, a full turn is required. Some couplings require wrench tightening; others are connected and disconnected by hand. Some installations require

12966

PRECAUTIONS: Aseptic technique must be maintained at all times. In inoculating the tomato plants it is recommended that the inoculating needle be pushed completely through the stem internode. Be careful that the inoculating needle is not excessively hot after flaming and prior to picking up the bacteria from the slant for inoculation.

TIME REQUIRED: 3-4 weeks.

RESULTS: Using the above procedures, colonies of *Agrobacterium tumefaciens* should be isolated readily from the streak plates with little contamination. The bacteria from the nutrient broth should exhibit motility in a hanging-drop preparation, although some strains of *A tumefaciens* are not motile. Gram staining should reveal the bacteria to be Gram-negative. Characteristic galls usually appear on the inoculated tomato plants about 2 weeks after inoculation. The bacteria isolated from these galls should have the same characteristics as the original isolate fulfilling Koch's postulates.

8. Inoculation with Sclerotinia sclerotiorum

OBJECTIVES: To demonstrate techniques required for successful inoculation with sclerotia of *Sclerotinia sclerotiorum* and to illustrate disease symptoms caused by the fungus.

MATERIALS: (Suggest that the experiment be carried out by the instructor as a demonstration.)
Two heads of lettuce; 20-25 sclerotia of *S. sclerotiorum*; 2 glass or plastic containers large enough to accommodate a head of lettuce; 1-1000 mercuric chloride solution or 1-20 chlorox solution; sterile water; paper towels; forceps.

PROCEDURE: Wipe out the plastic or glass containers with mercuric chloride or chlorox solution. Place several paper towels dampened with sterile water in the bottom of each container. Place lettuce head on top of damp paper towels. Place sclerotia in mercuric chloride solution or chlorox solution for five minutes and rinse in sterile water. With a flamed forceps, place sclerotia on one lettuce head in various positions in relation to the lettuce head and to individual leaves.

Keep second lettuce head uninoculated as a control.

Sterile water should be added to both containers every few days.

TIME REQUIRED: For severe symptoms to develop, two weeks are required.

RESULTS: Observations should be made daily and notes taken on (1) changes in appearance of the sclerotia; (2) changes in inoculated lettuce head; (3) any difference in appearance of the control.

When the inoculated lettuce head has completely broken down, the fungus will form new sclerotia. These may be collected, dried, placed in a jar to store and used in future experiments.

Figure 5-17.—Quick-disconnect coupling for air lines.

that the coupling be safetied with safety wire, others do not require any form of safetying. Because of these individual differences, all quick disconnects should be installed in accordance with the instructions in the applicable technical publication.

A typical quick disconnect coupling for hydraulic systems is illustrated in figure 5-18. Each coupling consists of two halves, referred to as the S1 half and the S4 half. When disconnected, the union nut remains with the S1 half. The S4 half has a mounting flange (9) for attaching to a bulkhead or other structural member.

All parts referred to in the following paragraph are identified in figure 5-18. The two halves of the coupling may be connected by placing the tubular valve (1) within the protruding nose (6) of the mating half and rotating the union nut in a clockwise direction. The union nut must be rotated until the teeth (5) fully engage the lock spring (8). A properly tightened coupling will have compressed the lock spring until a 1/16-inch minimum gap exists between the inside lip of the spring retainer fingers and the spring plate. Figure 5-19 shows the coupling both properly tightened and improperly tightened.

The locking action may be followed by referring to figure 5-18. Positive locking is assured by the locking spring (8) with teeth which engage ratchet teeth on the union nut (5) when the coupling is fully connected. The lock

1. Tubular valve.
2. Valve spring.
3. O-ring packing.
4. Sleeve.
5. Union nut teeth.
6. Protruding nose.
7. Poppet valve.
8. Lock spring.
9. Mounting flange.

Figure 5-18.—Typical quick-disconnect coupling.

12967

spring automatically disengages when the union nut is unscrewed. An O-ring packing (3) seals against leakage as the coupling halves are joined. Positive opening of the valves occurs as the halves are connected.

When the coupling halves are joined, the protruding nose (6) of the S4 half contacts the sleeve (4) of the S1 half. Simultaneously, the head of the tubular valve (1) contacts the face of the poppet valve (7), thus preventing foreign matter from entering the system.

Tightening the union pulls the coupling halves together. This causes the nose of the S4 half to push the sleeve into the S1 half, uncovering the ports of the tubular valve. At the same time, the head of the tubular valve depresses the poppet valve.

When the coupling halves are fully connected, the sleeve and poppet valve have reached the positions shown in the left-hand view of figure 5-19. The nose of the S4 half has engaged the O-ring packing of the S1 half, providing a positive sleeve.

Dust caps are usually provided with quick-disconnect couplings to cover the ends of the coupling when it is separated.

It should be emphasized that regardless of the type of lines or connectors used to make up a fluid power system, make certain that they are the correct size and strength, and perfectly clean on the inside. Circulatory systems must be absolutely clean and free from scale and other foreign matter. Iron or steel pipes, tubing, and fittings can be cleaned with boiler tube wire brush or with commercial pipe cleaning apparatus. Rust and scale can be removed from short straight pieces by sandblasting, provided there is not danger that sand particles will remain lodged in blind holes or pockets after the piece is flushed. In the case of long pieces or pieces bent to complex shapes, rust and scale can be removed by pickling (cleaning metal in a chemical bath). Parts must be degreased prior to pickling. The manufacturer of the parts should provide complete pickling instructions.

Open ends of pipes, tubing, hose, and fittings should be capped or plugged when they are to be stored for any considerable period. Rags or waste must not be used for this purpose, because they deposit harmful lint which can cause severe damage to the fluid power system.

Figure 5-19.—Quick-disconnect coupling properly and improperly tightened.

12968 TABEL

CHAPTER 6

RESERVOIRS, STRAINERS, FILTERS, AND ACCUMULATORS

Fluid power systems must have a sufficient supply of noncontaminated fluid for the efficient operation of the systems. The components which provide these requirements for hydraulic systems differ to some extent from the similar components of pneumatic systems. Because of these differences, it is necessary to cover the components separately under each system.

HYDRAULIC SYSTEM COMPONENTS

An adequate supply of the recommended liquid is a very important requirement for the efficient operation of a hydraulic system. The liquid must be kept clean and free of air. The components used to accomplish these requirements are described in the following paragraphs.

RESERVOIRS

The reservoir is a basic component of any hydraulic system. Although its primary function is to provide a storage space for the hydraulic liquid required by the system, a well constructed reservoir provides a number of additional functions. Among these functions are dissipation of heat, trapping of foreign matter, and the separation of air from the system. In most systems the reservoir is a separate component of the system, while in other systems, for example an automatic transmission of an automobile, the reservoir also serves as the housing for the complete system.

Reservoirs dissipate heat by radiation from the external walls or by use of internal or external radiating devices such as cooling coils or fins. The trapping of foreign matter usually requires the use of filters and strainers which are discussed later in this chapter. The separation of air from the system is accomplished by the design of the reservoir which includes the incorporation of baffles to slow the liquid as it returns to the reservoir. The air bubbles have a greater chance of escaping to the surface of the liquid if the liquid moves at a slow velocity.

Many factors are considered when selecting the size and configuration of a hydraulic reservoir. The reservoir must be large enough to store more than the anticipated volume of liquid that the system will require. The recommended reservoir volume is usually based on the gallon-per-minute flow demanded by the system. A reservoir capacity equal to two or three times the maximum rate of flow required by the system is usually sufficient. A higher ratio is desirable for fixed installations, and a somewhat lower ratio may be required for mobile equipment. Adequate space must be allowed to accommodate thermal expansion of the hydraulic liquid and changes in liquid level due to system operation.

Reservoirs are of two general types—nonpressurized and pressurized. Nonpressurized reservoirs are vented to the atmosphere to prevent a vacuum from being formed as the liquid level in the reservoir is lowered. The vent also makes it possible for any air that has entered the system to find a means of escape.

Aircraft and missiles which are designed for high-altitude operation require pressurized reservoirs. Pressurizing assures a positive flow of liquid to the pump at altitudes where low atmospheric pressure is encountered.

Nonpressurized Reservoirs

Hydraulic systems used to operate equipment which is located at or near sea level are normally equipped with nonpressurized reservoirs. This includes the hydraulic systems of ground and ship installations and some aircraft which are limited to low altitude operations.

A typical reservoir for use with ground and ship installations is illustrated in figure 6-1. This type reservoir is made of hot rolled steel

12969

Figure 6-1.—Nonpressurized reservoir (ground or ship installation).

plates and welded joints. The ends of the tank extend below the bottom of the reservoir and serve as the support. The bottom of the reservoir is concave and a drain plug is incorporated at the lowest point.

Large removable covers are installed on each end of the reservoir to provide easy access for cleaning. One of the covers contains a liquid level indicator and a filler opening with a chained cap. Since the liquid level must be checked frequently, the indicator is located in a position where it can easily be read. A strainer is installed in the filler neck to keep foreign matter from entering the reservoir when new liquid is added.

In this type reservoir a baffle plate extends lengthwise through the center of the tank and separates the pump supply line from the system return. The baffle usually extends from the bottom of the tank to approximately two-thirds the height of the normal liquid level. The purpose of the baffle is not to completely divide the reservoir into separate compartments, but rather to reduce turbulence created by return flow and prevent the continuous recirculation of the same liquid. It also allows foreign matter to settle to the bottom of the compartment and air bubbles to escape through the surface of the liquid before the liquid is recirculated.

The vent (air breather) line contains a filter to purify the air. Some vent assemblies contain a bypass check valve. The vent assembly functions to allow the pressure in the reservoir to balance with atmospheric pressure and to filter the air which is drawn in when the liquid level is lowered due to system operation. The check valve allows air to be expelled from the reservoir at a greater rate than normal when large volumes of liquid are returned to the reservoir, and it also prevents unfiltered air from being drawn into the reservoir.

12970

The pump supply line enters the reservoir at the top and extends to within a few inches of the reservoir bottom. Return lines must be well below the liquid surface level to prevent foaming. The end of the return line is usually cut at an angle of approximately 45 degrees and positioned so that the flow is directed toward the walls of the tank and away from the pump intake line. This provides for maximum heat dissipation.

The inside of the reservoir is painted with a sealer to minimize oxidation which can be caused by condensation. The sealer must be of a composition which will not react chemically with the liquid specified for the system.

Because of the design of this type reservoir, a large portion of the harmful contaminants in the system will accumulate in the reservoir. Therefore, the reservoir should be periodically drained and flushed with a solvent compatible with the liquid being used in the system. After cleaning, the reservoir should be filled to the proper level with clean hydraulic liquid of the type that conforms to the specification to be used in the system. The system must be operated for a few minutes to allow the liquid to displace the air in the system. The liquid level must then be rechecked and more liquid added if necessary. In some systems it is necessary to have air bleed valves to provide a means for trapped air to escape from the system. The automobile brake system is a good example of the use of these bleed valves.

As mentioned earlier in this chapter, some aircraft hydraulic systems are equipped with nonpressurized reservoirs. Figure 6-2 is a typical example of the nonpressurized reservoirs used in aircraft systems. Because of weight limitations required in aircraft construction, the reservoirs are made of welded aluminum alloy. There are two pump supply line outlets—one supplies the main power pump, while the other outlet supplies the emergency pump. The outlet which supplies the main power pump is located a considerable distance above the outlet which supplies the emergency pump. If leakage, such as the result of a ruptured line, occurs during normal operation, a reserve supply of liquid will remain in the reservoir to supply the emergency pump. The reserve supply of liquid should be of sufficient volume to operate the subsystems necessary for a safe landing of the aircraft. This includes such operations as the extension of the landing gear and lowering the landing flaps.

Figure 6-2.—Nonpressurized reservoir (aircraft system).

Maintenance of this reservoir consists mainly of cleaning the filler neck strainer and replacement of the vent filter. The filler neck strainer should be cleaned with a cleaning fluid that is compatible with the liquid used in the system. When cleaning the strainer, inspect for broken mesh (sometimes the result of servicing with a funnel).

The vent filter element should be replaced in accordance with applicable technical publications. Additional information on strainers and filters is presented later in this chapter.

The cleanliness of the reservoir is maintained by periodic flushing similar to the procedures described in chapter 3.

Pressurized Reservoirs

Many of the Navy's aircraft and missile hydraulic systems are equipped with pressurized reservoirs. This assures a positive flow of liquid to the pump at high altitudes where low atmospheric pressures are encountered. There are two common types of pressurized reservoirs—air-pressurized and liquid-pressurized.

AIR-PRESSURIZED.—In the air-pressurized reservoir, air pressure is introduced into the top of the reservoir. The air pressure is

12971

187 OF 327

ED

056 238

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

usually provided by bleed air taken from the compressor section of the engine. An example of an air-pressurized reservoir is illustrated in figure 6-3.

The air is filtered and the pressure is regulated to the required psi before it enters the top of the reservoir. The required pressure is stipulated by the manufacturer. As the liquid level in the reservoir changes (through the operation of a subsystem) the regulator maintains a constant pressure by increasing the airflow to the reservoir, or by venting the excess reservoir air pressure to the atmosphere.

Provisions are incorporated to fill the reservoir from a single point. Filling is accomplished by forcing hydraulic liquid into the filler line. Applicable technical instructions must be adhered to when servicing this type reservoir.

LIQUID-PRESSURIZED.—Some hydraulic systems use system hydraulic pressure for pressurizing the reservoir. A reservoir of this type is shown in figure 6-4. This type reservoir is divided into two compartments by a floating piston. The floating piston is forced downward in the reservoir by a spring and by a pressure probe which fits into the piston.

The pressure probe is connected to the pump pressure line so that when the system is pressurized, pressure enters the probe and aids the springs in pressurizing the liquid in the lower compartment. This pressurizes the pump supply line and the reservoir return line to the same pressure. This pressure prevents pump starvation at all altitudes.

This type reservoir has five ports—pump supply, return, pump pressure, reservoir drain, and overboard drain. Liquid is supplied to the pump through the pump supply port. Liquid returns to the reservoir from the system through the return port. Pressure from the system enters the pressure probe in the top of the reservoir through the pump pressure port. The reservoir drain port is for the purpose of draining the reservoir, when draining is necessary. The overboard drain port is equipped with a sight gage which is used in determining when the reservoir is full. When servicing the reservoir, a container should be placed under the overboard drain port, and liquid should be pumped into the reservoir until air-free liquid flows through the sight gage. (Air-free liquid is liquid containing no air bubbles.)

An indicator rod that protrudes through the top of the reservoir housing is used in determining when the reservoir needs servicing. The word REFILL is stamped on the rod guide. When the reservoir is full, the rod is extended and the word REFILL is hidden; when the rod is retracted, the word REFILL is exposed and the reservoir needs servicing.

Figure 6-3.—Air-pressurized reservoir.

FILTRATION OF HYDRAULIC LIQUIDS

The importance of keeping hydraulic liquid clean and free of contaminants cannot be overemphasized. Foreign matter in the system can cause excessive wear, increase power loss, clog control valves, and substantially increase maintenance and replacement costs. Although great care is taken while servicing, maintaining, and operating hydraulic systems, it is impossible to prevent some foreign matter from entering the system. Also, tiny particles of metal are deposited in the liquid during the normal wear of valves, pumps, and other system components. Filtering devices are incorporated in hydraulic systems to remove as much of this foreign matter as possible.

12972 1237

187

Figure 6-4.—Liquid-pressurized reservoir.

The filtering devices used in hydraulic systems are most commonly referred to as strainers and filters. Since they share a common function, the terms strainer and filter are often used interchangeably. Devices used to remove large particles of foreign matter from hydraulic liquids are normally referred to as strainers, while those used to remove the smallest particles are referred to as filters.

Strainers

Strainers usually consist of a metal frame wrapped with a fine mesh wire screen, or a screening element made up of varying thickness of specially processed wire. A typical strainer is illustrated in figure 6-5.

Strainers do not provide as fine a screening action as filters, but offer less resistance to flow. Therefore, strainers are usually used in pump inlet lines where restriction of flow would result in starvation of the pump. Strainers are also used in the filler necks of some hydraulic reservoirs.

Various arrangements for using strainers in a pump supply line are illustrated in figure 6-6. If one strainer causes excessive restriction of flow to the pump, two or more may be used in parallel as shown. Since strainers must be removed frequently for cleaning, they need only be hand tightened during installation, provided the fittings will remain submerged during the operation of the system. Pump inlet fittings exposed to air must be airtight.

Filters

The most common devices incorporated in hydraulic systems to prevent foreign particles and contaminating substances from remaining

12973

in the system are referred to as filters. They may be located within the reservoir, in the pressure line, in the return line, or in any other location where the designer of the system decides that they are needed to safeguard the hydraulic system against impurities.

Filters are classified as full flow or proportional flow. In a full flow type filter, all the liquid which enters the unit passes through the filtering element, while in a proportional flow type, only a portion of the liquid passes through the element.

FULL FLOW FILTER.—A full flow filter is illustrated in figure 6-7. This type of filter provides a positive filtering action; however, it offers resistance to flow, particularly when the element becomes dirty. For this reason a full flow filter usually contains a valve to automatically bypass the element when it cannot handle all the flow through the unit.

Figure 6-5.—Typical hydraulic system strainer.

Hydraulic liquid enters the filter through the inlet port in the body and flows around the element inside the filter bowl. Filtering takes place as the liquid passes through the filtering element and into the hollow core, leaving the dirt and impurities on the outside of the filter element. Filtered liquid then flows from the hollow core to the outlet port in the body and into the system.

The bypass pressure relief valve in the body allows the liquid to bypass the filter element and pass directly through the outlet port in the event that the filter element becomes clogged. In most filters of this type, the relief valve will open when a differential pressure of 50 psi has been built up. For example, if the pressure at the filter inlet port is 90 psi, and the pressure at the outlet port drops below 40 psi, the relief valve will open and allow the liquid to bypass the element. Additional information on the operation of relief valves is presented in chapter 10 of this course.

Some nonbypassing filters are equipped with a contamination indicator which works under the principle of difference in pressure between the fluid entering the filter and the pressure after it leaves the element. As contaminating particles collect on the filter element, the differential pressure across the element increases. When the increase in pressure reaches a specific value, an indicator (usually in the filter head) pops out, signifying that the element

Figure 6-6.—Various arrangements of hydraulic system strainers.

12974

Figure 6-7.—Full flow hydraulic filter.

must be cleaned or replaced. A low temperature lockout feature is incorporated in some types of contamination indicators to prevent actuation below 20° F, and thus eliminate the possibility of false indications due to cold weather.

The use of the nonbypassing type filter eliminates the possibility of contaminated liquid passing the filter element and contaminating the entire system. This type filter will minimize the necessity for flushing the entire system and lessen the possibility of other components in the system to fail.

PROPORTIONAL FLOW FILTER.—Figure 6-8 illustrates a proportional flow type filter. This type of filter operates on the venturi principle. (See glossary.) As the liquid passes through the venturi throat a drop in pressure is created at the narrowest point. This decrease in pressure causes a siphoning action which draws a portion of the liquid down around the cartridge through the filter element and up into the venturi throat. Filtering is provided for either direction of flow. Although only a portion of the liquid is filtered during each cycle, constant recirculation through the system will eventually cause all the liquid to pass through the filter element.

Filter Elements

The effectiveness of any filter is measured by the degree of filtration it produces. Degree of filtration means that a specific filter element will, when new and clean, stop a certain percentage of the particles which measure a certain size or larger, while the liquid is operating under its designed flow conditions.

The unit of measurement used in expressing the degree of filtration is the micron. A micron equals one-millionth of a meter, or 0.00004 inch. For comparison value, consider that the normal lower level of visibility to the naked eye is about 40 microns. (A grain of table salt is about 100 microns in size; the thickness of a human hair is about 70 microns; and a grain of talcum powder is about 10 microns in size.)

Some hydraulic systems require a much finer degree of cleanliness than other systems. This is due to closer tolerances required in some systems, such as the precisely mated parts in the servomechanisms of missiles. Some systems only require that 98 percent of the particles over 100 microns in size are removed, while other systems require that 100 percent of the particles measuring 2 or more microns are removed. The degree of filtration of a filter depends on the material and design of the filter element.

Filter elements are made of various materials, such as cellulose paper (micronic), plastic, porous metal, clay, and fuller's earth. Some of the different types of filter elements are described in the following paragraphs.

FULLER'S EARTH.—Fuller's earth is a clay-like material consisting of very fine particles and is used in the purification of mineral or vegetable base oils. It produces a fine degree of filtration; however, its use as a filtering element in present day hydraulic systems is limited. Filters employing fuller's earth or activated clay should not be used with hydraulic liquids containing additives, because such filters may remove the additives as well as the impurities.

MICRONIC.—Micronic, a term derived from the word micron, could be used to describe any filter element. Through usage, this term has become associated with a specific type filter with a filtering element made of a specially treated cellulose paper. The paper is formed

GLOSSARY

ANTIBIOTIC - a substance produced by a living organism which is antagonistic to another organism.

ASEXUALLY - producing new individuals without sex.

BACTERIA - small rod-shaped, usually single-celled plants micro-organisms 2-4 microns long (a micron is one-thousandth of a millimeter).

BIOTIC - relating to life.

CAUSAL ORGANISM - produces a given disease under a certain set of circumstances.

CHLOROSIS - a yellowing of normally green tissue due to partial failure of chlorophyll to develop.

DEBILITATING - to impair the strength of, to enfeeble.

DELETERIOUS - hurtful, noxious.

DISEASE CYCLE - all the events involved in disease development, including various stages in development of the pathogen and the effect of the disease on the host.

DISSEMINATION - the spread of infectious material.

EPIDEMIC - common to, or affecting at the same time, many in a plant community.

EPIDERMIS - the outermost layer of cells of a leaf or other plant part.

EPIPHYTE - a plant that grows upon another plant which it uses as a mechanical support but not as a source of food.

ETIOLATION - yellowing of plants due to lack of light.

EXUDATE - any material or substance formed inside a plant and discharged through a natural opening or an injury.

FACULTATIVE PARASITE - an organism that can grow either on living or dead organic matter.

FACULTATIVE SAPROPHYTE - an organism which is ordinarily a parasite, but under certain conditions may live saprophytically.

FISSION - a spontaneous division of the body into two or more parts, each of which grows into a complete organism, as in bacteria.

FUMIGANT - a liquid or solid substance that forms vapors which destroy pathogens, insects, etc.

FUNGICIDE - a chemical that kills or inhibits fungi.

Figure 6-8.—Proportional flow hydraulic filter.

in vertical convolutions (wrinkles) and is made in a cylindrical pattern. (See fig. 6-9.) An internal spring holds the element in shape.

This type element is designed to prevent the passage of 99 percent of solids greater than 10 microns (0.000394 inch) in size. The element in the full flow filter illustrated in figure 6-7 is of this design.

The element is normally thrown away when removed. It is replaced at periodic intervals in accordance with the applicable technical instructions. The element is replaced in the following manner:

1. Relieve system pressure.

2. Remove the bowl from the filter body. In some systems, such as aircraft hydraulic systems, the bowl is safetywired to the body and the wire must be cut for removal.

3. Remove the filter element from the filter body with a slight rocking motion. Do not twist the element.

4. Replace the element with a new one whenever possible. If a new element is not available, the old element may be cleaned, inspected, and reinstalled.

NOTE: A used micronic filter element may be cleaned by masking the element outlet and

1297

Figure 6-9.—Micronic filter element.

rinsing it with a cleaning solvent which is compatible with the liquid used in the system. After cleaning, inspect carefully to insure that there are no holes in the paper walls of the element.

5. Replace all old O-ring packings and backup washers with new ones.

6. Reinstall the bowl on the head assembly. Do not tighten bowl excessively; handtight is usually sufficient.

7. Pressurize the system and check the filter assembly for leaks. Safetywire if required.

POROUS METAL.—The porous metal element consists of minute metal balls joined together as one solid piece, but still remaining porous. The process of joining the balls is known as the sintered process. The metal used for this element is usually bronze or stainless steel. The element is capable of filtering particles greater than 5 microns, or approximately 0.0002 inch in size.

The design and operation of the porous metal filter is very similar to the micronic filter. Most porous metal filters are equipped with either the bypass relief valve or the contamination indicator described earlier in this chapter.

The porous metal element may be cleaned, tested, and reused. Cleaning is usually accomplished by backflushing clean liquid through the element. Special equipment is used for cleaning and inspection. Current applicable technical instructions must be consulted whenever cleaning and inspection of a porous metal filter element is necessary.

Some hydraulic systems have magnetic filters installed at strategic points. Filters of this type are designed primarily to trap any magnetic metal particles that may be in the system.

ACCUMULATORS

Hydraulic accumulators are incorporated in hydraulic systems to store a volume of liquid under pressure for subsequent conversion into useful work. This potential energy may be in the form of gravitation, the elasticity of springs, or the compressibility of gases.

Dead-Weight Accumulator

The dead-weight or gravity type accumulator represents the earliest form of accumulators and is generally used as a single unit to operate a multiple battery of hydraulic machines.

This accumulator consists of a vertical cylinder with a smoothly ground bore into which is fitted a piston with suitable packing. (See fig. 6-10.) A platform is mounted on top of the piston on which is placed a high density material, such as concrete blocks, metal, or stone. The force of gravity provides energy to force the liquid from the cylinder to the hydraulic system. The main advantage of this type accumulator is the pressure is constant regardless of the amount of liquid in the cylinder as the weight of the material on top of the cylinder remains constant. The main disadvantage of the dead-weight accumulator is its cumbersome size and weight.

Spring-Operated Accumulator

The spring-operated accumulator is similar in principle and design to the dead-weight type, except that spring compression supplies the weight pressure. Figure 6-11 depicts two examples of spring-operated accumulators.

The load characteristics of a spring are such that the energy storage depends on the force required to compress the spring. The uncompressed length of the spring represents zero energy storage.

In this type accumulator the compression resulting from the maximum installed length of the spring or springs should provide the

12977

Figure 6-10.—Dead-weight accumulator.

minimum pressure required of the liquid in the cylinder assembly. As liquid is pumped into the cylinder, the piston is forced up and the spring or springs are further compressed, thus providing a reservoir of potential energy for later use.

Air-Operated Accumulators

The air-operated accumulator is often referred to as pneumatic or hydropneumatic accumulator. This type accumulator utilizes compressed gas (usually air or nitrogen) to apply force to the stored liquid. Air-operated accumulators are classified as either separator or nonseparator types.

In the nonseparator type, no means are provided for separating the gas from the liquid. It consists of a fully enclosed cylinder, mounted in a vertical position, containing a liquid inlet port on the bottom and a pneumatic charging port at the top. Figure 6-12 depicts a nonseparator type of air-operated accumulator.

There must be some hydraulic liquid trapped in the bottom of the cylinder when this type accumulator is placed in service. Nitrogen or compressed air is then charged into the top of the cylinder until the pressure is equivalent to the minimum system requirements. As the system forces liquid into the bottom of the cylinder, the gas is further compressed and this compressed gas is then used as the energy medium. Only about 70 percent of the accumulator liquid volume is used in the system, as the remaining space must act as a separator to prevent the gas from entering the hydraulic system.

In the separator type of air-operated accumulator, a means is provided to separate the gas from the liquid. Three types of separators are bladder or bag, diaphragm, and piston (cylinder).

BLADDER OR BAG.—Figure 6-13 illustrates one version of an air-operated accumulator of the bladder type. This accumulator derives its name from the shape of the synthetic rubber bladder or bag which separates the liquid and gas within the accumulator. The accumulator consists of a seamless high-pressure shell, cylindrical in shape with domed ends. The bladder is fully enclosed in the shell and is molded to an air stem in the upper end of the shell. The air stem contains a high-pressure air valve. The bottom end of the shell is sealed with a special plug assembly containing the liquid port and usually a safety feature which makes it impossible to disassemble the accumulator with pressure on the system.

The bladder is larger in diameter at the top and gradually tapers to a smaller diameter at the bottom. The synthetic rubber is thinner at the top of the bladder than at the bottom. The operation of the accumulator is based on Barlow's formula for hoop stress which states: the stress in a circle is directly proportional to its diameter and wall thickness. This means that for a certain wall thickness, a large diameter circle will stretch faster than a small diameter circle; or for a certain diameter, a thin wall hoop will stretch faster than a thick wall hoop. Thus, the bladder will stretch around the top at its largest diameter and thinnest wall thickness, and will gradually stretch downward and push itself outward against the side walls of the shell. As a result it will squeeze out all the

12978

Figure 6-11.—Spring-operated accumulators.

liquid from the accumulator and consequently the bladder accumulator has very high volumetric efficiency. (A high volumetric efficiency is the ability to utilize a large percentage of the stored liquid to do work.)

DIAPHRAGM.—Although there are various modifications of this type accumulator, it is usually spherical in shape. Figure 6-14 illustrates an example of this type. The shell is constructed of two metal hemispheres which are either screwed or bolted together. The fluid and gas chambers are separated by a synthetic rubber diaphragm. An air valve to pressurize the accumulator is located in the gas chamber end of the sphere, and the liquid port to the hydraulic system is located on the other end of the sphere. This accumulator operates very similar to the bladder type.

CYLINDER.—The cylindrical accumulator contains a free-floating piston (fig. 6-15) which separates the air and hydraulic liquid chambers. The cylindrical accumulator consists of a barrel assembly, a piston assembly, and two end cap assemblies. The barrel assembly houses the piston and incorporates provisions for securing the end caps. The piston contains two packings. (See chapter 8 for information about packings.) A drilled passage in the piston provides for lubrication of the seal on the air chamber side.

In operation of the pneumatic type accumulators, the compressed air chamber is inflated with air or nitrogen to a predetermined pressure which is somewhat lower than system pressure. This pressure is stipulated by the system manufacturer. This initial charge of gas is referred to as accumulator preload.

As an example of accumulator operation, assume that an accumulator is designed for a preload of 600 psi in a 1,500 psi system.

The hydraulic system pressure should be zero when the initial charge of 600 psi preload is introduced into the air chamber of the accumulator. Some accumulators are equipped with air pressure gages for checking the preload. When the accumulator is not so equipped, a suitable high-pressure air gage must be installed at the air preload fitting for this purpose. As air pressure is applied through the air pressure port, it moves the separator (bladder, diaphragm, or piston) toward the opposite end. After the accumulator has been preloaded to 600 psi the hydraulic system is operated and the pump will force liquid into the accumulator until the pressure is 1,500 psi (system operating pressure). This compresses the gas until it occupies less than one-half the space that it did at 600 psi.

12979

Figure 6-12.—Air-operated accumulator (nonseparator type).

Figure 6-13.—Air-operated bladder type accumulator.

When actuation of hydraulic circuits lowers system pressure, it is evident that the compressed gas will expand against the separator, forcing hydraulic liquid from the accumulator, thus supplying an instantaneous supply of liquid to the hydraulic system.

Pneumatic accumulators should be visually examined for indications of external hydraulic leaks periodically. They should then be examined for external air leaks by brushing the exterior with soapy water, which will form bubbles where the air leaks occur.

The air valve assembly should be loosened to examine the accumulator for internal leaks. If hydraulic liquid comes out of the air valve, it indicates a leak in the separator. This is caused by a ruptured bladder or diaphragm, or by faulty packing on the piston type. As a result the accumulator must be removed, repaired, and reinstalled.

Before removing an accumulator from the system for repairs, all internal pressure must be relieved. The pumps must be turned off and system pressure relieved by actuating some part of the system until all pressure is dissipated. The preload is released by unscrewing the air valve fitting very slowly for approximately two revolutions so that the air or gas will escape gradually.

Applications

Many of the present day hydraulic systems are equipped with one or more accumulators. This storage of liquid under pressure serves several purposes in hydraulic systems, some of which are described briefly in the following

12980

Figure 6-14.—Diaphragm accumulator.

paragraphs. Some of the hydraulic systems illustrated and described in chapter 13 of this course show the applications of accumulators and their relationship to other components of the system.

LEAKAGE COMPENSATOR.—In some operations it is necessary to maintain the hydraulic system under a controlled pressure for a long period of time. It is very difficult to maintain a closed system without some leakage, either external or internal. Even a small leak can decrease the required pressure. By the proper use of an accumulator, this leakage can be compensated for and the pressure maintained within an acceptable range for long periods of time. In the same manner, the accumulator can compensate for thermal expansion and contraction of the liquid due to variations of temperature.

SHOCK ABSORBER.—A liquid, flowing at a high velocity in a pipe, will create a backward surge when stopped suddenly by the closing of a valve and thus develop instantaneous pressures two and three times the operating pressure of the system. This shock will result in objectional noise and vibration which can cause considerable damage to piping, fittings, and components. The incorporation of an accumulator will enable such shock and surges to be absorbed or cushioned by the entrapped gas, thereby reducing their effects. The accumulator will also dampen pressure surges which are caused by the pulsating fluid delivery from the pump.

AID TO PUMP.—There are times when most hydraulic systems require large volumes of liquid for short periods of time. This is due to large cylinders or the necessity of operating two or more circuits simultaneously. It is not economical to incorporate a pump of such capacity in the system for only intermittent usage to supply these applications, particularly if there are sufficient intervals during the working cycle for an accumulator to store up a volume of liquid to aid the pump during these peak demands.

EMERGENCY POWER SUPPLY.—The energy stored in an accumulator may be used to actuate a unit in the event of normal hydraulic system failure. For example, in an aircraft hydraulic system, sufficient energy can be stored in the accumulator for several applications of the wheel brakes.

PNEUMATIC SYSTEM COMPONENTS

Like hydraulic systems, pneumatic systems require an adequate supply of clean fluid for the efficient operation of the system. In addition, the gas used in pneumatic systems must be as free of moisture as possible.

RECEIVERS

Receiver, storage cylinder, air bottle, and air cylinder are all terms used to describe the component of a pneumatic system which provides the functions similar to those provided by the reservoir of a hydraulic system. As described earlier in this chapter, the hydraulic reservoir supplies the liquid to the pump and provides a place for the return liquid from the system. In pneumatic systems the receiver stores a volume of gas under the maximum pressure required by the system and supplies it to the system as needed. In many systems air is forced into the receiver by an air compressor which is part of the system. (See chapter 7 for detailed information about air compressors.) In other systems the receiver is a storage cylinder or bottle which is charged from some outside source.

Receiver is the term usually associated with ground and shipboard pneumatic systems which employ a compressor as part of the system.

Figure 6-15.—Cylinder (piston) accumulator.

The receiver is located near the compressor and is often considered as part of the compressor.

The receiver acts as a storage tank and also as a supply tank. When the demand for air pressure is in excess of the compressor capacity, some of the air from the receiver enters the system. When the demand is less than the compressor capacity, the excess air enters the receiver. Thus, in a pneumatic system, the receiver functions to maintain the system at a constant pressure and thereby retards the length of the start-stop-start cycles of the compressor.

The size and construction of the receiver depend on the maximum pressure and volume of air required to efficiently operate the complete system. The receiver is cylindrical in shape and may be mounted either horizontally or vertically, the position and location being dependent on the space available for installation. Vertically mounted receivers should have bottom heads of convex shape to permit proper draining of accumulations of moisture, oil, and foreign matter. Each receiver should be fitted with the following accessories and connections:

1. Inlet and outlet connections.
2. Drain connections and valve.
3. Connection for operating line to compressor regulator.
4. Pressure gage.
5. Relief valve.
6. Manhole or handhole plate, depending on size of receiver.

The inlet connection should be located near the top of the receiver and the outlet line to the system taken from a point above the bottom of the receiver. The line between the compressor and receiver should be kept as short and as free from bends as possible in order to eliminate excessive vibration due to the pulsations of air and to reduce loss of pressure due to friction.

The receivers in aircraft pneumatic systems are referred to as storage cylinders or bottles. The compressed air or nitrogen is stored in these cylinders until required by actuating the system. The cylinders are initially charged with compressed air or nitrogen from an external source. Most systems contain air compressors which replace the pressure and volume

12982

lost through leakage, thermal expansion, and system operation.

The storage cylinders are either spherical or cylindrical in shape. The cylinders are nonshatterable and each is equipped with a manual moisture drain valve for periodic draining of the moisture or bleeding air from the cylinder. Cylinders are provided in different sizes the selection of which depends on the requirements of the system. The required size is stipulated by the manufacturer of the system. The unit of measurement to indicate the volume of cylinders is the cubic inch. The pressure normally required in aircraft pneumatic systems is 3,000 psi. Figure 6-16 illustrates an example of a storage cylinder used in an aircraft pneumatic system.

FILTRATION OF PNEUMATIC GASES

Clean, dry gas is required for the efficient operation of pneumatic systems. Free air, satisfying these requirements adequately, is seldom found. The atmosphere contains dust and impurities in various amounts, depending on the locality. Also, the atmosphere generally contains a substantial amount of moisture in vapor form.

Figure 6-16.—Storage cylinder for an aircraft pneumatic system.

Solids, such as dust, rust, or pipe scale in pneumatic systems may lead to excessive wear, failure of components, or in some cases prevent the pneumatic devices from operating. Moisture is also very harmful to the system. It washes lubrication from moving parts, thereby aiding corrosion and causing excessive wear of components. Moisture will also settle in low spots in the system and freeze during cold weather, causing stoppages of the system or rupture of transmission lines.

As discussed in chapter 3, the use of nitrogen decreases these hazards to some extent. However, it is not economically feasible to use nitrogen, except in small systems.

An ideal filter would remove all dirt and moisture from a pneumatic system without causing a pressure drop in the process. Obviously, such a condition can only be approached; it cannot be attained.

Removal of Solids

Air filters are similar in design and operation to the hydraulic filters discussed earlier in this chapter. Some materials used in the manufacture of elements for air filters are woven screen wire, steel wool, fiber glass, and felt fabrics. Elements made of these materials are often used in the units that filter the air as it enters the compressors. They are used in the same manner as carburetor filters on automobiles. These filters must be checked frequently for the accumulation of foreign matter and the elements cleaned and replaced as necessary. If the filter element becomes clogged, the compressor is reduced in efficiency or, in extreme cases, becomes inoperative. Filters of this type are usually designed to remove particles as small as 25 microns.

Porous metals and ceramic elements are used in filters which are installed in the compressed air supply lines. These filters also use a controlled airpath to provide some filtration. Internal design causes the air to flow in a centrifugal path within the bowl. (See fig. 6-17.) Heavy particles and water droplets are thrown out from the airstream and drop to the bottom

12983

Figure 6-17.—Air filter.

Figure 6-18.—Air filter using rotating blades as element.

of the bowl. The air then flows through the filter element, which filters out most of the smaller particles. The filter is designed with a drain valve at the bottom of the bowl. When the valve is opened with air pressure on the system, the accumulation of solids and water will be blown out of the bowl. Many air filters have transparent bowls so that accumulation of impurities can be seen. Some units provide for automatic drainage.

An air filter which employs moving mechanical devices as an element is illustrated in figure 6-18. As the compressed air passes through the filter the force revolves a number of multiblade rotors at high speed. Moisture and dirt are caught on the blades of the rotors. The whirling blades hurl the impurities by centrifugal force to the outer rims of the rotors and to the inner walls of the filter housing. Here, contaminating matter is out of the airstream and falls to the bottom of the bowl where it must be drained at periodic intervals.

The removal of solids from pneumatic systems is generally accomplished either by screening, centrifugal force, or a combination of the two. Design features of these filters may vary, but the principles of operation remain the same. To maintain their efficiency, filters must be cleaned or replaced as often as operating conditions require.

Removal of Moisture

When drawn into the compressor, air contains a certain amount of moisture in vapor form. During the compression operation the temperature and pressure of the air increase and the moisture remains in vapor form. If the moisture would remain in vapor form it would have very little effect on the system. However, as the compressed air cools, the moisture vapor condenses into water. When it is in this condensed state, moisture causes corrosion and rust, dilutes lubricants, and may freeze in the lines.

Cooling of the compressed air causes the moisture to condense. Therefore, cooling devices are normally installed immediately after the compressor before the air enters the receiver and goes on into the system. There is a water separator fitted on the discharge side of the cooler. As the air is cooled, the moisture condenses and is removed from the system as the air passes through the water separator. The separators are of a variety of designs. The removal of liquid is accomplished by centrifugal force, impact, or sudden changes in velocity of the air-stream. Many water separators are

86642383

similar in design and operation to the air filter illustrated in figure 6-18.

Chemical driers are incorporated in some pneumatic systems. Their purpose is to absorb any moisture that may collect in the lines after the moisture separator. Each drier contains a cartridge of an absorbent chemical such as silica-gel. The cartridge should be blue in color. If otherwise noted, the cartridge is to be considered contaminated with moisture and should be replaced.

10285

FUNGUS - a group of plants lacking chlorophyll, reproducing by sexual or asexual spores, and consisting primarily of mycelium.

GALL - a pronounced localized swelling; an outgrowth, often more or less spherical, consisting of unorganized cells.

GERM TUBE - the thread-like filament (hypha) produced by a fungus spore when it begins to grow.

GERMICIDE - a substance that kills micro-organisms.

GERMINATION - the beginning of growth.

HERBICIDE - a chemical that kills or inhibits green plants.

HOST - the plant which is invaded or parasitized by a disease-producing agent from which the parasite obtains its sustenance.

HOST RANGE - the various kinds of plants that a particular parasite may affect.

HYBRIDIZATION - to produce or cause to produce hybrids.

HYPERPLASIA - abnormal increase in the number of cells resulting in the formation of galls or tumors.

HYPERTROPHY - abnormal increase in the size of an organ or tissue brought about by the enlargement of the cells or by an increased cell division or both.

HYPHA - one of the thread-like strands, or filaments, that constitute the body (mycelium) of a fungus.

HYPOPLASIA - undergrowth, stunting or dwarfing.

IMMUNITY - the ability of a plant to remain free from a disease by virtue of inherent properties of the plant.

IMMUNIZATION - to render immune.

INCUBATION PERIOD - the period of time between the inoculation of a plant by a disease producing agent and the appearance of symptoms.

INFECTION - to become established in a parasitic relationship with a host plant.

INFESTATION - the presence of disease in a population of plants or of pathogens where they can produce a disease.

INGRESS - to gain entrance into plant tissue.

INOCULATE - to bring infectious material (the inoculum) in contact with a host plant.

INOCULUM - infectious material, disease producing substance.

1296

CHAPTER 7

PUMPS AND COMPRESSORS

The heart of any fluid power system is the component which generates the force required by the fluid to move the actuating devices. Pumps are utilized to provide this requirement in hydraulic systems; while compressors are used in pneumatic systems. Although pumps and compressors serve a similar purpose, the principles of operation and the design differ to some extent. Due to these differences, the two components are discussed separately in this chapter.

PUMPS

Pumps are used for a number of essential services in the Navy. Pumps supply water to the boilers, draw condensation from condensers, supply sea water to the firemain, circulate cooling water for coolers and condensers, pump out bilges, transfer fuel oil, supply water to the distilling plants, and serve many other purposes. Although the pumps discussed in this chapter are those used in hydraulic systems, the principles of operation of the different types apply to the pumps used in other systems.

PURPOSE

Hydraulic pumps are devices for converting mechanical energy into hydraulic energy. Many different sources are used to provide the mechanical energy to the pumps. Electric motors, air motors, and gasoline engines are all used as a source of power to operate hydraulic pumps. Some pumps are manually operated. Many of the pumps in aircraft hydraulic systems are attached to and driven by the engine.

The purpose of a hydraulic pump is to supply a flow of liquid to the hydraulic system. A pump does not create pressure. As it provides flow, the pump transmits a force to the liquid. Although the force is generated by the pump, it is not controlled by the pump. Pressure can be created only by a restriction to the flow of liquid from the pump. The pressure is controlled by the load imposed on the system or the action of a pressure regulating device.

In order for a pump to create a flow of liquid to the outlet port and into the system it must have a continuous supply of liquid available to the inlet port. Atmospheric pressure (discussed in chapter 2) plays an important role in the supply of liquid to the inlet port. If the pump is located below the reservoir, the force of gravity supplements atmospheric pressure. However, in most systems the pump is located above the reservoir. Aircraft and missiles which operate at high altitudes are equipped with pressurized hydraulic reservoirs (see chapter 6) to compensate for low atmospheric pressure encountered at high altitudes.

As the pump forces liquid through the outlet port, a suction is created at the inlet port. Suction is defined as a partial vacuum or low-pressure area. This low-pressure area contains a pressure lower than the atmospheric pressure (approximately 14.7 psi at sea level). When the pressure at the inlet port of the pump is lower than the local atmospheric pressure, the atmospheric pressure acting on the liquid in the reservoir forces the liquid into the pump.

PUMP PERFORMANCE

Pumps are normally rated in terms of volumetric output and pressure. The volumetric output is the amount of liquid the pump can deliver to its outlet port in a certain period of time at a given speed. Volumetric output is usually expressed in gallons per minute (gpm). Changes in pump speed affect volumetric output. Therefore, some pumps are rated according to displacement at a certain pressure. Pump displacement is the amount of liquid a pump can

12886

Figure 7-1.—Centrifugal force.

If the buckets are shaped like pieces of pie, and they completely fill the circle, as shown in figure 7-1 (B), then the buckets will act as a paddle wheel revolving in a drum-shaped container. The result is a continuous liquid pressure due to the centrifugal force over all circumference of the container. The pressure is the result of the restriction to the flow of the liquid caused by the walls of the container.

By enlarging the diameter of the container (fig. 7-1 (C)), a space (A) is created for liquid between the ends of the paddles and the drum. The rotation of the liquid in the buckets, because of centrifugal force, pushes outward against the liquid bottom and thereby imparts a pressure to the liquid in space (A). If the liquid remains stationary—which would not actually be the case in practice—then it would be subjected to a true static pressure the magnitude of which would be dependent upon the centrifugal force of the liquid between the paddles.

If an opening were provided in the containing drum, this force would cause the liquid in space (A) to be discharged. If the liquid in space (A) were stationary, this discharge could take any direction because, according to Pascal's law, static pressure in a fluid is transmitted equally in all directions. In practice, however, another factor must be considered which determines the direction of discharge. This factor is explained shortly.

If a means for continuously filling the bucket is provided, such as a central opening in the container, and a source of power to rotate the paddles is provided, then a continuous flow, as shown in figure 7-1 (D), exists. This demonstrates one of the principles which applies to the operation of the centrifugal pump.

When a force which is compelling an object to move in a curved path is removed, the object will travel in a straight line with the speed and direction it had at the instant the force is removed. This is illustrated in figure 7-2. An object is attached to a line (R) and swung around in a circular path. Assume that the line breaks when it reaches the vertical position shown. The object will then fly off horizontally (at right angles to the line) with the velocity it had at that moment. This horizontal path will be tangent to the circular path the object was following up to this moment, so this action is commonly called "going off on a tangent", while the velocity is called tangential velocity.

Figure 7-2.—Tangential velocity.

This is the principle of the old fashioned sling shot, in which a man placed a stone in a leather holder to which two strings were attached, swung it around his head to impart velocity, and then let go one of the strings. This principle is utilized in the centrifugal pump in addition to the outward action of centrifugal force previously described.

Referring to figure 7-1 (D), it is clear that as soon as some of the liquid in space (A) is permitted to escape, a continuous suction or low-pressure area will be set up in the center opening. (This center opening is commonly referred to as the eye.) Atmospheric pressure or gravity force acting on the liquid in the reservoir will force liquid to the eye of the container. The blades or paddles will then start rotating the liquid. As the liquid in space (A) flows out of the container, the liquid between the blades will move out to a greater and greater radius. In so doing it will acquire an increasing tangential velocity, because the angular velocity of the blades is constant, and as the radius of the path circle increases, the liquid must travel a greater distance per revolution. Eventually, it will reach the tip of the blades and enter space (A), which is equivalent to "going off on a tangent" as described earlier. The liquid will also tend to continue moving directly outward from the center of the circle because of its inertia. (See glossary.) The two actions—centrifugal and tangential—are then combined.

This liquid which is thrown off the tips of the blades has a velocity equal to the tangential velocity it had the instant it left them. The two actions—centrifugal force and tangential velocity—cause the liquid to flow out of the discharge port.

Since it is part of the meaning of velocity that it have direction (see chapter 2), the direction in which the discharge takes place becomes important. In order to make the most use of the velocity, the discharge is generally in an approximately tangential direction.

The liquid is thrown off the paddles, or impeller blades, as they are called in the pump, all around the circle. Therefore, liquid is being added to the space (A) at all points, but is escaping from it at only one point. In order to compensate for this, it is customary to increase the area of space (A) as the outlet is approached. By this means it is also possible to slow down the tangential velocity at a more gradual rate, and thereby obtain more efficient conversion of the velocity in the pump into flow to the system. Therefore, it is customary to give space (A) a shape like that shown in figure 7-3. This shape—called a volute—continuously expands in a definite ratio. The details of the size and shape of the volute used are very important to the efficiency of the pump, as are likewise the exact shape, size, and speed of rotation of the impeller. In general, it is true that impeller blades that curve backward with respect to their direction of rotation give better results than straight blades, but the reasons for this and for other details of construction are matters which concern the designer primarily, and are outside, the scope of this course.

Types

The two most common types of centrifugal pumps used in hydraulic systems are the volute

12989

Figure 7-3.—Basic elements of a centrifugal pump.

and diffuser types. In both types flow is provided by the action of centrifugal force. At the same time the rotation of the impeller produces the greater part of the velocity which drives the liquid out through the discharge. The major differences between these two types are described in the following paragraphs.

VOLUTE TYPE.—Figure 7-4 illustrates the principles of operation of a volute type centrifugal pump. The impeller discharges the liquid at a high velocity into a progressively expanding casing. This contour of the casing directs the movement of the liquid through the outlet port and into the system.

DIFFUSER TYPE.—Figure 7-5 illustrates the diffuser type pump. It is similar in design to the volute pump, with the addition of a series of stationary blades incorporated around the outside circumference of the impeller blades. These stationary blades are termed the diffuser. The diffuser blades are curved in the opposite direction from the rotating impeller blades. The diffuser reduces the velocity of the liquid and decreases slippage (previously described), which increases the efficiency of the pump.

Classification

Centrifugal pumps are classified in several ways. For example, they may be either single-stage or multistage. A single-stage pump has only one impeller. A multistage pump has two or more impellers housed together in one casing.

Figure 7-4.—Volute type centrifugal pump.

Figure 7-5.—Diffuser type centrifugal pump.

As a rule, each impeller acts separately, discharging to the suction of the next stage impeller. For the sake of compactness the several impellers of multistage pumps are almost invariably placed on one shaft. Figure 7-6 shows a possible flow diagram for a four-stage pump.

Centrifugal pumps are also classified as horizontal or vertical, depending upon the position of the pump shaft.

The impellers used on centrifugal pumps may be classified as single-suction or double-suction. The single-suction impeller allows liquid to enter the eye from one direction only; the double-suction type allows liquid to enter the eye from two directions. Impellers are also classified as CLOSED or OPEN. Closed

12990

Figure 7-6.—Flow diagram of a four-stage centrifugal pump.

impellers have side walls which extend from the eye to the outer edge of the blade tips; open impellers do not have these side walls.

Manufacturers sometimes classify centrifugal pumps according to the size and shape of the casing, arrangement of the discharge nozzle in relation to the pumping chamber, and the type of material used in the construction of the pump.

Centrifugal pumps may be driven by any of the sources mentioned previously in this chapter. Many of the pumps aboard ship are driven by steam turbines. As a rule, high-pressure centrifugal pumps are direct-drive—that is, the impeller rotates at the same rpm as the power source. However, some low-pressure centrifugal pumps have reduction gears installed between the power source and the impeller. This allows the power source to operate at a high speed and the impeller to operate at a lower speed, thus obtaining maximum efficiency from both the power source and the pump.

Applications

Centrigual pumps are nonpositive displacement pumps. They are used in hydraulic systems which require a large volume of flow and operate at relatively low pressures. Some hydraulic systems require variations of flow and pressure. A centrifugal pump is sometimes used in combination with a positive displacement pump to supply the demands of such systems. The positive displacement pump maintains the system during periods requiring low volume and high pressure. The centrifugal pump aids the positive displacement pump when the system requires large volumes and low pressure.

In some hydraulic systems a centrifugal pump is used with a variable displacement pump. Both pumps are driven by the same electric motor. The motor is fully enclosed and is cooled by a flow of liquid from the centrifugal pump. The centrifugal pump also provides a supply of liquid to the inlet port of the variable displacement pump. This insures an adequate supply of liquid to the main system pump (variable displacement) for all demands of the system.

ROTARY PUMPS

All rotary pumps work by means of rotating parts which trap the fluid at the suction side and force it through the discharge outlet. Gears, screws, lobes, vanes, and cam-and-plunger arrangements are commonly used as elements in rotary pumps. Rotary pumps operate on the positive displacement principle—that is, each rotation or each stroke delivers a definite quantity of liquid.

Rotary pumps are designed with very small clearances between rotating parts and between rotating parts and stationary parts, in order to minimize slippage from the discharge side back to the suction side. Rotary pumps are designed to operate at relatively moderate speeds in order to maintain these clearances. Operation at higher speeds causes erosion and excessive wear, resulting in increased clearances.

Classification

Like centrifugal pumps, there are numerous types of rotary pumps and various methods of classification. They may be classified as to shaft positions—either vertically or horizontally mounted; the type of drive—electric motor, gasoline engine, etc.; manufacturer's name; or service application. However, classification of rotary pumps is generally made according to the type of rotating element. A few of the most common types of rotary pumps are discussed in the following paragraphs.

GEAR.—The simple gear pump (fig. 7-7) consists of two meshed gears which revolve in a housing. The drive gear in the illustration is turned by a drive shaft which engages the power source. The clearances between the gear teeth as they mesh and between the teeth and the pump housing are very small.

The inlet port is connected to the reservoir supply line, and the outlet port is connected to

1299

Figure 7-7.—Gear type rotary pump.

the pressure line. In the illustration, the drive gear is turning in a counterclockwise direction, and the driven (idle) gear is turning in a clockwise direction. As the teeth pass the inlet port, liquid is trapped between the teeth and the housing. This liquid is carried around the housing to the outlet port. As the teeth mesh again, the liquid between the teeth is displaced into the outlet port. This action produces a positive flow of liquid into the pressure lines. A shearpin or shear section that will break under excessive loads is incorporated in the drive shaft. This is to protect the power source or reduction gears if the pump fails because of excessive load or jamming of parts.

The gears of the pump illustrated in figure 7-7 are referred to as spur gears. Herringbone and helical gears are also used in the construction of gear pumps.

The herringbone gear pump (fig. 7-8) is a modification of the simple gear pump. The liquid is pumped in the same manner as in the simple spur gear pump. In this type pump, one discharge phase begins before the previous discharge phase is entirely complete. This overlapping and the relatively larger space at the center of the gears tend to minimize pulsations and give a steadier flow than is found in the spur gear pump.

The helical gear pump is still another modification of the simple gear pump. Because of the helical gear design, the overlapping of successive discharges from spaces between the teeth is even greater than it is in the herringbone gear pump; and the discharge flow is, accordingly, even smoother. Since the discharge flow is smooth in the helical gear pump, the gears can be designed with a small number of large teeth—thus allowing increased capacity without sacrificing smoothness of flow.

Figure 7-9 shows a helical gear pump. The pumping gears in this type of pump are driven by a set of timing and driving gears, which also function to maintain the required close clearances while preventing actual metallic contact

12992

Figure 7-8.—Herringbone gear pump.

between the pumping gears. (Metallic contact between the teeth of the pumping gears would provide a tighter seal against slippage; but it would cause rapid wear of the teeth, because foreign matter in the liquid would be present on the contact surfaces.)

Roller bearings at both ends of the gear shafts maintain proper alignment and minimize the friction loss in the transmission of power. Packings are used to prevent leakage around the shaft.

The spur, herringbone, and helical are all classed as external gear pumps. This is because both sets of teeth project outward from the center of the gears. In an internal gear pump, the teeth of one gear project outward, but the teeth of the other gear project inward toward the center of the pump, as shown in figure 7-10 (A). One gear wheel stands inside the other in an internal gear pump. A gear of this kind can rotate, or be rotated by, a suitably constructed companion gear.

One type of internal gear pump is illustrated in figure 7-10 (B). The external gear is directly attached to the drive shaft of the pump and is placed off-center in relation to the internal gear. The two gears mesh on one side of the pump chamber, between the suction and the discharge. On the opposite side of the chamber a crescent-shaped form stands in the space between the two gears in such a way as to provide a close tolerance with them.

182293

Figure 7-9.—Helical gear pump.

The rotation of the center gear by the shaft causes the outside gear to rotate, since the two are in mesh. Everything in the chamber rotates except the crescent, causing liquid to be trapped in the gear spaces as they pass the crescent. The liquid is carried from the suction to the discharge, where it is forced out of the pump by the meshing of the gears. As the liquid is carried away from the intake side of the pump, the pressure is diminished, and liquid is forced in from the source of supply. The size of the crescent that separates the internal and external gears is the determining factor in the volume delivery of this pump. A small crescent allows more volume of liquid per revolution than a larger crescent.

An internal gear pump of quite another construction is illustrated in figures 7-11 and 7-12. This pump consists of a pair of gear-shaped elements, one within the other, mounted in the pump chamber. The inner gear is directly connected to the drive shaft of the source of power.

Figure 7-10.—Off-centered, internal gear pump.

Figure 7-11.—Centered internal gear pump.

12994

Figure 7-12.—Principles of operation of the internal gear pump.

How the gears operate to give a pumping action is shown in figure 7-12. The inner gear has one fewer teeth than the outer gear. The tooth form of each gear is related to that of the other in such a way that each tooth of the inner gear is always in sliding contact with the surface of the outer gear. Each meshing pair of teeth of the two gears definitely engages at just one place in the pump. In the illustration this place is at the top (X) so that tooth 1 will be in mesh with tooth 2, tooth 3 in mesh with tooth 4, and so on, when each pair reaches position (X).

At one side of the point of mesh, pockets of increasing size are formed as the gears rotate, while on the other side the pockets decrease in size. The pockets of increasing size are suction pockets, while those of decreasing size are discharging pockets. In figure 7-12 the pockets on the right-hand side of the drawings are increasing in size as one moves down the illustration, while those on the left-hand side are decreasing in size. The intake side of the pump would therefore be to the right and the discharge to the left. In figure 7-11, since the right-hand side of the drawing was turned over to show the ports, the intake and discharge appear reversed. Actually, A in one drawing covers A in the other.

LOBE.—The principle of operation of a lobe pump is exactly the same as for the external gear pump already described. The lobes are considerably larger than gear teeth, but there are only two or three lobes on each rotor. Figure 7-13 illustrates a three-lobe pump. The two elements are rotated, one being directly driven by the source of power, and the other through timing gears. As the elements rotate, liquid is caught between each lobe and the wall of the pump chamber, and carried around from the suction side to the discharge side of the pump. As each volume of liquid leaves the intake chamber, the

Figure 7-13.—Lobe pump.

12995

INVASION - growth or movement of an infectious agent into a plant and its establishment in it.

INNOCUOUS - harmless, producing no ill effect or injury.

LESION - a localized spot of diseased tissue.

LIFE CYCLE, LIFE HISTORY - the complete succession of events in the life of an organism.

LOCAL INFECTION - infection involving only a limited part of a plant.

MACRO - a combining form meaning large.

MICRO - a combining form meaning small.

MOSAIC - a plant disease caused by a virus and generally characterized by irregular light and dark green areas in the leaves.

MOTTLE - an irregular pattern of light and dark areas.

MUMMY - a dried, shriveled fruit, the result of some fungus disease.

MYCELIUM - the vegative body of the fungus, an aggregate of many hyphae.

NECROSIS - death, dead plant tissue.

NEMATOCIDE - a chemical that kills nematodes.

NEMATODE - a small invertebrate animal (often called roundworm) that seldom exceeds one-eighth inch in length. Nematodes may feed on plant parts.

NODULE - a lump, knot, or tubercle.

OBLIGATE PARASITE - an organism that must complete its active growth and reproduction upon or in its respective host.

PARASITE - an organism that obtains its nutrients wholly or in part from another living organism.

PATHOGEN - any organism capable of causing disease.

PATHOGENESIS - the part of the life of a disease-producing organism when it is directly associated with a living host.

PATHOLOGIST - one who studies diseases.

PENETRATION - same as invasion.

PESTICIDE - any agent that destroys pests, such as a fungicide, insecticide, etc.

pH - a symbol of a scale used to designate the relative acidity of a solution.

1297

pressure in the intake chamber is lowered, and additional liquid is forced into the chamber from the source of supply.

The lobes are so constructed that there is a continuous seal at the point of juncture at the center of the pump. The lobes of the pump illustrated in figure 7-13 are fitted with small vanes at the outer edge to improve the seal of the pump. Although these vanes are mechanically held in their slots, they are, to some extent, free to move outward. Centrifugal force keeps the vanes snug against the chamber and the other rotating members.

VANE.—Figure 7-14 illustrates a vane pump of the unbalance design. The rotor of this pump is slotted and is rotated by the drive shaft. Each slot of the rotor is fitted with a rectangular vane. These vanes are, to some extent, free to move outward in the slot. The rotor and vanes are enclosed in a housing, the inner surface of which is offset with the drive shaft axis. As the rotor turns, centrifugal force keeps the vanes snug against the wall of the housing. The vanes divide the area between the rotor and housing into a series of chambers. The chambers vary in size according to their respective positions around the shaft. The inlet port is located in that part of the pump where the chambers are expanding in size so that the partial vacuum formed by this expansion draws the liquid into the pump. The liquid is trapped between the vanes and is carried to the outlet side of the pump. The chambers contract in size on the outlet side, and this action forces the liquid through the outlet port and into the system.

The pump is figure 7-14 is referred to as unbalanced because all of the pumping action takes place on one side of the shaft and rotor. This causes a side load on the shaft and rotor. Some vane pumps are constructed with an elliptical shaped housing which forms two separate pumping areas on opposite sides of the rotor. This cancels out the side loads; therefore, this pump is referred to as a balanced vane pump.

Figure 7-14.—Vane pump.

Application

Although some rotary pumps are capable of operating in high-pressure systems (above 1,500 psi), their use is normally limited to systems which operate at pressures of 1,500 psi or below. As compared to other hydraulic pumps, rotary pumps are less expensive, have fewer moving parts, and feature simplicity in design and construction.

The efficiency of rotary pumps depends on the close tolerances between the rotating elements and, in most pumps, between the rotors and the housing of the pump. This efficiency is quickly reduced by excessive wear. For this reason dirt picked up by the liquid must be eliminated by suitable filters.

Rotary pumps are often used in hydraulic systems which do not require the continuous, or near continuous, operation of the pump. For example, electric-driven gear pumps are often used to operate the emergency hydraulic systems in aircraft. This provides an efficient pump to supply fluid to the system in case of main system failure. It is far less expensive than the type pump generally used in the main system and due to its limited use, maintains efficiency.

RECIPROCATING PUMPS

A reciprocating pump depends upon a reciprocating (back-and-forth) motion to transmit liquid from the inlet port to the outlet port. In this type pump, this motion involves the back-and-forth motion of pistons inside of cylinders. Reciprocating pumps, like rotary pumps, operate on the positive displacement principle—that is, each stroke delivers a definite volume of liquid to the system.

12998

Classification

The master cylinder of the automobile brake system and the hand water pump, both of which are described and illustrated in chapter 4, are examples of simple reciprocating pumps. Reciprocating pumps of this type are usually classified as:

1. Direct- or indirect-acting.
2. Simplex (single) or duplex (double).
3. Single- or double-action.
4. Vertical or horizontal.

Figure 7-15 illustrates a manually operated reciprocating pump. This type pump is often used as an emergency pump in a hydraulic system. It is a direct-acting pump, because the pump rod is a direct extension of the piston.

Figure 7-15.—Hydraulic hand pump.

This pump is referred to as a simplex because it has only one cylinder. A double or duplex pump is an assembly of two single pumps placed side by side on the same foundation. Duplex pumps are seldom used with modern equipment.

In a single-action pump the liquid is drawn into the cylinder on the first or suction stroke and is forced out of the cylinder on the return or discharge stroke. The pump illustrated in figure 7-15 is a double-action pump. When the piston is moved to the left, the force of the liquid in the outlet chamber and spring tension causes check valve (A) to close. This movement causes the piston to force the liquid in the outlet chamber through the outlet port (D) and into the system. This same movement of the piston causes a low-pressure area in the inlet chamber. Atmospheric pressure acting on the liquid in the reservoir transmits this pressure to the liquid at the inlet port (C). This differential of pressures acting on the ball of check valve (B) causes the spring to compress and open the check valve. This allows liquid to enter the inlet chamber.

When the piston completes this stroke to the left, the inlet chamber is full of liquid. This liquid eliminates the low pressure area in the inlet chamber thereby allowing spring tension to close check valve (B).

When the piston is moved to the right, the force of the confined liquid in the inlet chamber acts on the ball of check valve (A). This action compresses the spring and opens check valve (A), allowing the liquid to flow from the intake chamber to the outlet chamber. Because of the area occupied by the piston rod, the outlet chamber cannot contain all the liquid discharged from the inlet chamber. Liquid will not compress; therefore, the extra liquid is forced out port (D) into the system. Because each stroke of the pump forces liquid into the system, this type pump is referred to as a double-action pump.

This pump is classified as horizontal because the piston moves back and forth on a horizontal plane. If the piston moves up and down, the pump is classified as a vertical pump.

Two other classes of reciprocating pumps are the radial-piston and the axial-piston. These pumps are often classified as rotary-piston pumps, because a rotary motion is imparted to the pumps by the source of power. However, the actual pumping is performed by sets of pistons reciprocating inside sets of cylinders.

RADIAL-PISTON PUMPS.—Figure 7-16 illustrates the operation of the radial-piston pump. The pump consists of a pintle which remains stationary and acts as a valve; a cylinder block which revolves around the pintle and contains the cylinders in which the pistons operate; a rotor which houses the reaction ring of hardened steel against which the piston heads press; and a slide block which is used to control the length of the piston strokes. The slide block does not revolve but houses and supports the rotor, which does revolve due to the friction set up by the sliding action between the piston heads and the reaction ring. A drive shaft is secured to the cylinder block.

In figure 7-16 (A) assume liquid is in space (X) in one of the cylinders of the cylinder block when the piston is at position (1). If the cylinder block and piston are rotated in a clockwise direction, the piston is forced into its cylinder as it approaches position (2). This action reduces the volumetric size of the cylinder and forces a quantity of liquid out of the cylinder and into the outlet port above the pintle. The

1997

Figure 7-16.—Principles of operation of the radial-piston pump.

pumping action is due to the fact that the rotor, in the slide block, is offcentered in relation to the center of the cylinder block.

In figure 7-16 (B) the piston has reached position (2) and has pushed the liquid through the outlet port. The cylinder outlet is blocked as the piston moves from position (2) to (3). No pumping or suction will occur while the piston and cylinder are passing over the solid part of the pintle. After the piston moves to position (3), however, it starts drawing liquid into the cylinder as the rotation of the cylinder block moves the piston to position (4). At this point the cylinder has taken on a full charge of liquid. The pistons are driven out of the cylinder block by centrifugal force as the cylinder block is revolved. As the piston moves across the pintle, no intake or discharge of liquid occurs. After the piston has passed the pintle and starts toward position (2) another discharge takes place. Alternate intake and discharge continues as the rotor is revolved about its axis—intake on one side of the pintle and discharge on the other side, as the piston slides in and out. The piston head is held against the reaction ring of the rotor by centrifugal force.

In figures 7-16 (A) and (B) the center point of the rotor is different from the center point of the cylinder block. It is the difference of these centers that produces the pumping action. If the rotor is moved so that its center point is the same as that of the cylinder block, as shown in figure 7-16 (C), there is no pumping action, since the piston does not move back and forth in the cylinder as it rotates with the cylinder block.

The flow in this pump can be reversed by moving the slide block, and therefore the rotor, to the right so that the relation of the centers of the rotor and the cylinder block are reversed from the position shown in figures 7-16 (A) and (B). Figure 7-16 (D) shows this arrangement. The piston draws liquid in as it travels from position (1) to position (2) and pumps liquid out as it travels from (3) to (4).

In the illustrations the rotor is shown in the center, the extreme right, or the extreme left in relation to the cylinder block. The amount of adjustment in distance between the two centers determines the amount of liquid pumped. This difference determines the length of the piston stroke, which controls the amount of liquid flow in or out of the cylinders. This adjustment may be controlled in different ways. Manual control by means of a handwheel is the

412998

simplest. The pump illustrated in figure 7-16 is controlled in this way. For automatic control of delivery to accommodate varying volume requirements during the operating cycle, a hydraulically controlled cylinder may be used to position the slide block. A gear-motor controlled by a push-button or limit switch is sometimes used for this purpose.

A pump of this type with only one piston would not be practical. Therefore, the cylinder contains several pistons. Note that the pump illustrated in figure 7-17 contains an odd number of pistons. This is because no more than one piston is completely blocked by the pintle at any one time. If there were an even number of pistons spaced evenly around the cylinder block; for example, eight, there would be occasions when two of the pistons would be blocked by the pintle, while at other times none would be blocked. This would cause three pistons to discharge at one time and four at one time, causing pulsation in flow. With an odd number of pistons spaced evenly around the cylinder block, only one piston is completely blocked by the pintle at any one time. This reduces pulsations of flow.

Some of the principal parts of the radial-piston pump are described in more detail in the following paragraphs.

Pintle.—In figure 7-16 the pintle is shown, for the sake of simplicity, as a flat bar around which the rotor turns. Actually, the pintle is a

Figure 7-17.—Nine piston radial-piston pump.

12999

round bar which serves as a stationary shaft around which the cylinder block turns. The pintle shaft, as shown in figure 7-18, has four holes bored from one end lengthwise through part of its length. Two holes serve as the intake and the remaining two as the discharge. Two slots are cut in the side of the shaft so that each slot connects two of the lengthwise holes. The two slots are in line with the pistons when the cylinder block is assembled on the pintle. One of these slots provides the path for the liquid to pass from the pistons to the discharge holes bored in the pintle. The other slot connects the two inlet holes to the pistons when they are drawing in liquid. The discharge holes are connected through appropriate fittings to a discharge line so that the liquid can be directed into the system. The other pair of holes are connected to the inlet line.

Cylinder Block.—This is a block of metal with a hole bored through its center to fit the pintle and cylinder holes bored equal distances apart, around its outside edge. The cylinder holes connect with the hole that receives the pintle. The relationship for one kind of pump is shown in figure 7-19. Though cylinder blocks may differ in design, they all serve the same purpose. Some appear to be almost solid, while others have spokelike cylinders radiating out from the center. Both the cylinder holes and the pintle holes are very accurately machined so that liquid loss around the piston is kept to a minimum.

Pistons.—Like cylinder blocks, pistons are manufactured in different designs. Some of these designs are illustrated in figure 7-20. View (A) shows a piston with small wheels that roll around the inside curve of the rotor. View (B) shows a piston in which the conical edge of the top bears directly against the reaction ring of the rotor. In this particular design, while the piston is going back and forth in the cylinder, it will also rotate about its axis, so that the top surface will wear uniformly. View (C) shows a piston attached to curved plates. The curved plates bear against and slide around the inside surface of the rotor. The sides of the pistons are accurately machined to fit the cylinders, so there is a minimum loss of liquid between the walls of the piston and cylinder. No provision is made for the use of piston rings to help seal against piston leakage.

Rotor.—Here again, the design may be different from pump to pump, as shown in figure 7-21. The rotor consists essentially of a circular ring, machine finished on the inside, against which the pistons bear. The rotor rotates within the slide block which can be shifted

Figure 7-19.—Cylinder block for radial-piston pump.

Figure 7-18.—Pintle for radial-piston pump.

13866

Figure 7-21.—Rotors for radial-piston pumps.

from side to side in order to control the length of stroke of the pistons. The slide block has two pairs of machined surfaces on the exterior so that it can slide in tracks in the pump case. The sliding motion is controlled by any of the means covered earlier in this chapter.

These parts, together with the drive shaft, constitute the main working parts of the pump. The drive shaft is connected to the cylinder block and is driven by an outside force such as an electric motor.

AXIAL-PISTON PUMPS.—Axial piston pumps have the same general characteristics as radial-piston pumps. However, in the axial-piston pump, the block with its pistons rotate on a shaft in such a way that the pistons reciprocate in their cylinders along lines parallel to the axis of the shaft. This is called axial motion.

The pumping action of this type pump is made possible by a universal joint or link. Figure 7-22 is a series of drawings which illustrate how the universal joint is used in the operation of the axial-piston pump.

First, a rocker arm is installed on a horizontal shaft. (See fig. 7-22 (A).) The arm is joined to the shaft by a pin in such a way that it can be swung back and forth. Next, a ring is placed around the shaft and secured to the rocker arm so that the ring can turn from left to right as shown in figure 7-22 (B). This makes it possible to get two rotary motions in different planes at the same time, and in varying proportions as may be desired. The rocker arm can swing back and forth in one arc, and the ring can simultaneously move from left to right in another arc, in a plane at right angles to the plane in which the rocker arm moves.

Next, a tilting plate is added to the assembly. The tilting plate is placed at a slant to the axis of the shaft, as depicted in figure 7-22 (C). In

Figure 7-22.—Relationship of the universal joint in the operation of the axial-piston pump.

this position the rocker arm is slanted back at the same angle as the tilting plate, so that it lies parallel to the tilting plate. The ring is also parallel to the tilting plate and in contact with it. Its position in relation to the rocker arm is unchanged from that shown in figure 7-22 (B).

Figure 7-22 (D) shows the assembly after the shaft, still in a horizontal position, has been rotated a quarter turn. The rocker arm is still in the same plane as the tilting plate, and is now perpendicular to the axis of the

13001

shaft. The ring has turned on the rocker arm pins, so that it has changed its position in relation to the rocker arm, but it remains parallel to, and in contact with, the tilting plate.

Figure 7-22 (E) shows the assembly after the shaft has been rotated another quarter turn. The parts are now in the same position as shown in figure 7-22 (C), but with the ends of the rocker arms reversed. The ring still bears against the tilting plate.

As the shaft continues to rotate, the rocker arm and the ring turn about their pivots, with each changing its relation to the other, and with the ring always bearing on the plate.

Figure 7-22 (F) shows a wheel added to the assembly. The wheel is placed upright and fixed to the shaft, so that it rotates with the shaft. In addition, two rods, (A) and (B), are loosely connected to the tilting ring, and run through two holes standing opposite to each other in the fixed wheel. As the shaft is rotated, the fixed wheel runs perpendicular to the shaft at all times. The tilting ring rotates with the shaft and always remains tilted, since it remains in contact with the tilting plate. The distance along rod (A), from the tilting ring to the fixed wheel, is greater than the distance along rod (B). As the assembly is rotated, however, the distance along rod (A) will decrease as its point of attachment to the tilting ring comes closer to the fixed wheel, while the distance along rod (B) will increase. These changes continue until after a half revolution, at which time the initial position of the rods has been reversed. After another half revolution the two rods will again be in their original position.

As the assembly rotates, the rods are moved in and out through the holes in the fixed wheel. This is the way the axial-piston pump works. To get a pumping action, it is only necessary to place pistons at the ends of the rods, beyond the fixed wheel, and insert them in cylinders. The rods must be connected to the pistons and to the wheel by ball and socket joints. As the assembly rotates, each piston moves back and forth in its cylinder. Intake and discharge lines can be arranged so that liquid enters the cylinders while the spaces between the piston heads and the bases of the cylinders are increasing, and leaves the cylinders during the other half of each revolution, when the piston heads are moving in the opposite direction.

Figure 7-23 is an example of an axial-piston pump which illustrates the application of these operating principles. This type pump usually consists of a circular cylinder block with either 7 or 9 equally spaced pistons.

The main parts of the pump are the drive shaft, pistons, cylinder block, and valve plate. There are two ports in the valve plate. These ports connect directly to openings in the face of the cylinder block. Liquid is forced in one port by atmospheric pressure and forced out the other by the reciprocating action of the pistons.

There is a fill port in the top of the cylinder housing. This opening is normally kept plugged, but it can be opened for testing the pressure in the housing or case. When installing a new pump or newly repaired one, this plug must be removed and the housing filled with the recommended liquid before the pump is operated. There is a drain port in the mounting flange to drain away any leakage from the drive shaft oil seal.

When the drive shaft is rotated, it rotates the pistons and cylinder block with it. The offset position of the cylinder block causes the pistons to move back and forth in the cylinder block while the shaft, pistons, and cylinder block rotate together. As the pistons reciprocate in the cylinder block, they draw the liquid in one port and force it out the other.

In figure 7-24, piston (A) is shown at the bottom of the stroke. When piston (A) has rotated to the position held by piston (B), it will have moved upward in its cylinder, forcing liquid through the outlet port during the entire distance. During the remainder of the rotation back to its original position, the piston will be traveling downward in its cylinder, drawing the liquid through the inlet port. Since each one of the pistons will be performing the same operation in succession, liquid is constantly being taken into the cylinder bores through the inlet port and expelled from the cylinder bores into the pressure line of the system. This action creates a steady, nonpulsating flow of liquid.

As shown in figure 7-22 (F), the distance the pistons move back and forth in their cylinders depends on the tilt or angle given to the tilting plate. In the pump illustrated in figures 7-23 and 7-24, this tilt or angle is fixed by the shape of the housing and therefore is referred to as a fixed or constant displacement pump. Pump output is determined by the angle and can be changed only by varying the pump speed.

With no tilt at all, no pumping action would occur since the pistons would not move back and forth. The distances (A) and (B) in figure

Figure 7-23.—Partial cutaway view of axial-piston pump.

7-22 (F) would be equal, and would remain equal as the assembly rotates. If the angle of tilt given to the tilting plate were reversed, making distance (A) less than distance (B), the pumping action would be reversed. What had been the discharge would now become the intake and vice versa. By adding a mechanism to control the angle at which the tilting plate stands, any variation in delivery can be obtained, from a maximum in one direction through zero delivery, to a maximum in the opposite direction, although the drive shaft continues to rotate at a constant speed.

The variable displacement (stroke) axial-piston pump, shown in figure 7-25, usually has either seven or nine single-acting pistons which are evenly spaced around a cylinder barrel. (Note that the term cylinder barrel, as used in this connection, actually refers to a cylinder block which holds all the cylinders.) The piston rods make a ball-and-socket connection with a socket ring. The socket ring rides on a thrust bearing carried by a casting—the tilting box or plate.

When the tilting box is at a right angle to the shaft, and the pump is rotating, the pistons do not reciprocate; therefore, no pumping action takes place. When the tilting box is tilted away from a right angle, however, the pistons reciprocate and the liquid is pumped.

Displacement of this type pump can be varied by changing the angle of the tilting box. Various methods are used to control the movement of the tilting box—manual, electric, pneumatic, or hydraulic. The operation of a hydraulically controlled variable displacement pump is included in the hydraulic power drive system in chapter 13.

Application

As stated previously, the manually operated reciprocating pump is used for emergency operation of hydraulic systems. They are commonly used in aircraft hydraulic systems for ground checking the hydraulic system in addition to their use for emergency operation.

Radial- and axial-piston pumps are commonly used for applications requiring high pressures and accurate control of the volume discharge. They are the most common type pump used in Navy hydraulic systems. Some piston pumps are designed to operate in systems requiring pressures of over 10,000 psi. However, most of the hydraulic systems in the Navy operate at pressures of 3,000 psi or less.

Variable displacement piston pumps are used in electro-hydraulic anchor windlasses, cranes and winches, the power transmitting unit in electro-hydraulic steering systems, and many other systems aboard ship.

Variable displacement axial-piston pumps are used in most aircraft hydraulic systems. Due to weight and space limitations, the design

13003

Figure 7-24.—Schematic diagram of axial-piston pump.

of these pumps differs to some extent as compared to the variable displacement pump previously described. The current edition of Navy Training Course, Aviation Structural Mechanic H 3 & 2, NavPers 10310 (Series), and applicable technical publications should be consulted for the description of these pumps.

AIR COMPRESSORS

Compressors are used in pneumatic systems to provide requirements similar to those required by pumps in hydraulic systems. They furnish compressed air as required to operate the units of pneumatic systems.

COMPRESSOR CLASSIFICATIONS

Air compressors are classified in various ways. A compressor may be single-acting or double-acting, single stage or multistage, and horizontal, angle, or vertical, as shown in figure 7-26. A compressor may be designed so that only one stage of compression takes place within one compressing element, or so that more than one stage takes place within one compressing element. In general, compressors are classified according to the type of compressing element, the source of driving power, the method by which the driving unit is connected to the compressor, and the pressure developed.

Types of Compressing Elements

Air compressor elements may be of the centrifugal, rotary, or reciprocating types. Most of the compressors used in the Navy have reciprocating elements (fig. 7-27). In this type compressor the air is compressed in one or more cylinders very much like the compression which takes place in an internal combustion engine.

Sources of Power

Compressors are driven by electric motors, internal combustion engines, steam turbines, reciprocating steam engines, or hydraulic motors. A majority of the air compressors in naval service are driven by electric motors.

Drive Connections

The driving unit may be connected to the compressor by one of several methods. When the compressor and the driving unit are mounted on the same shaft, they are close coupled. Close coupling is often used for small capacity compressors that are driven by electric motors. Flexible couplings are used to join the driving unit to the compressor where the speed of the compressor and the speed of the driving unit can be the same.

V-belt drives are commonly used with small, low-pressure, motor-driven compressors, and some medium-pressure compressors. In a few installations, a rigid coupling is used between the compressor and the motor. In a steam turbine drive, compressors are usually driven through reduction gears.

Pressure Classification

Compressors are classified as low-pressure, medium-pressure, or high-pressure.

Figure 7-25.—Variable displacement (stroke) axial-piston pump.

PHOTOSYNTHESIS - the complicated process by which green plants make organic substances from water and carbon dioxide of the air through the energy of sunlight.

PLANT DISEASE - any alteration of a plant that interferes with its normal structure, or function and renders the plant unfit for its normal use.

PLANT PATHOLOGY - the study of plant diseases.

PROGENY - offspring.

PUSTULE - a pimple-like or blister-like structure.

QUARANTINE - to isolate; to keep from normal relations due to contagious diseases or infections.

RESISTANCE - ability of a plant to remain relatively unaffected by a disease because of inherent properties it possesses.

SAPROPHYTE - an organism that feeds on dead organic matter.

SHOT HOLE - a symptom of disease in which small roundish fragments drop out of the leaves so that the leaves look as though they had been riddled by shot.

SOIL STERILIZATION - the process of treating soil so as to kill living things in it.

SPORE - the one-to-many celled reproductive unit of a fungus which corresponds to a seed in plants.

SPORULATION - the process of producing spores.

SPOT - a definite diseased area.

STOMA - a minute opening in a leaf or stem; a pore.

SUSCEPT - any plant liable to infection by a given disease-producing agent.

SUSCEPTIBILITY - lacking inherent ability to resist disease.

SYMBIOSIS - a mutually beneficial association of two or more organisms.

SYMPTOM - any reaction of the host plant to disease. Usually it refers to visible reactions.

SYSTEMIC - pertaining to a disease in which an infection leads to a general spread throughout the plant body. Could refer to the spread of a chemical.

TOLERANCE - the degree of endurance of a plant to the effects of adverse conditions, chemicals, or parasites. A tolerant plant is capable of sustaining a disease without serious injury or crop loss.

Figure 7-26.—Types of air compressors:
(A) Vertical; (B) horizontal; (C) angle; (D) duplex; (E) multistage.

13006

Figure 7-27.—A simple two-stage reciprocating low-pressure air compressor.

Low-pressure compressors are those which have a discharge pressure of 150 psi or less. Medium-pressure compressors are those which have a discharge pressure of 151 psi to 1,000 psi. Compressors which have a discharge pressure above 1,000 psi are classified as high-pressure.

Most low-pressure air compressors are of the two-stage type with either a vertical V (fig. 7-27) or a vertical W arrangement of cylinders. Two-stage, V-type, low-pressure compressors usually have one cylinder for the first (low-pressure) stage of compression, and one cylinder for the second (high-pressure) stage. W-type

13007

compressors have two cylinders for the first stage of compression and one cylinder for the second stage. This arrangement is shown in figure 7-28 (A).

Compressors may be classified according to a number of other design features or operating characteristics.

Medium-pressure air compressors are of the two-stage, vertical, duplex, single-acting type. Many medium-pressure compressors have differential pistons; this type of piston has more than one stage of compression on each piston. (See fig. 7-28 (A).)

Modern air compressors are generally motor-driven (direct or geared), liquid-cooled, four-stage, single-acting units with vertical or horizontal cylinders. Cylinder arrangements for high-pressure air compressors utilized in naval service are illustrated in figure 7-28 (B). Small capacity high-pressure air systems may have three-stage compressors. High capacity air systems may be equipped with five- or six-stage compressors.

RECIPROCATING AIR COMPRESSOR

Reciprocating air compressors are usually similar in design and operation. The following discussion relates to the radial, three-stage, piston type, high-pressure air compressor.

An air compressor assembly includes all the associated equipment required for delivering filtered, oil and moisture free compressed air as required for the operation of various units. The complete assembly normally includes the compressor, filter and separator assembly, an adjustable relief valve assembly, a control system, and an air receiver with a pressure gage attached. (See fig. 7-29.)

Principles of Operation

The air compressor consists of three piston type air pumps connected in series. Therefore, the process of compressing ambient air (see glossary) to a relatively high pressure is accomplished in three stages. Each compressor

Figure 7-28.—Air compressor cylinder arrangements:
(A) Low- and medium-pressure cylinders; (B) high-pressure cylinders.

13008

Figure 7-29.—Air compressor assembly.

stage consists of a cylinder, a reciprocating piston, and intake valve mechanism, and an exhaust valve mechanism. The reciprocating pistons are connected to, and actuated by, a master rod assembly attached to a shaft that is coupled to the power source by a flexible coupling. The intake and exhaust valve are usually hardened steel discs, carefully ground and lapped to seat snugly against a shoulder at the end of the cylinder bore (chamber). The valves are held against the valve seat by a tempered steel spring. As the piston travels downward, the cylinder bore forward of the piston is at a reduced pressure and the intake valve lifts from its seat and allows air to enter the area. As the piston travels upward, the intake valve closes and the air is compressed until the pressure overcomes the resistance of the exhaust valve spring. The exhaust valve is then lifted from its seat and the compressed air in the cylinder escapes through the outlet fitting into the interstage tubing.

To compensate for the volumetric decrease of the air as it is compressed, the cylinder bores and piston displacement of the three stages are progressively decreased. The first-stage cylinder is the largest, receiving a relatively large volume of ambient air and compressing it into a smaller volume for delivery to the medium sized second-stage cylinder. Here, the compression cycle is repeated, the supercharged inlet air being raised to a higher pressure and applied to the third-stage cylinder. The compression cycle is completed and the air is raised to its ultimate delivery pressure in the third-stage cylinder. (This is an application of Boyle's law discussed in chapter 2.)

NOTE: These cycles compare with the number of stages of a particular compressor. For example, a six-stage compressor has six such cycles.

Compressor Lubrication

Unlike hydraulic pumps, which are lubricated by the liquid of the system passing through the moving parts, the pneumatic compressor requires a lubrication system for its moving parts.

Most compressors are lubricated by a simple but effective combination of pressure, splash, and mist principles. Normally the compressor base is used as the oil sump and oil pump housing. The oil level can be measured by a dip stick, or an oil level sight gage may be mounted on the outside of the base.

During compressor operation, sump oil enters the pump cylinders through ports in the cylinder walls on the up stroke of the piston. On the downstroke, the piston descends past the ports, preventing the escape of oil. The oil trapped in the cylinder is forced through a spray tube and is directed against the rapidly moving master rod. The impact forms a fine oil mist which fills the interior of the crankcase and provides lubrication of the master rod, bearing, pistons, connecting links, and other internal parts. Internal lubrication of the cylinders and valve mechanisms is aided by the small quantity of vapor drawn into the first-stage cylinder from the crankcase and passed on to the second and third stages through the interstage connecting tubes.

1300

Cooling

In some low-pressure air compressors the heat which normally results from rapid compression of a gas is dissipated before the temperature attains a troublesome level. This is accomplished by using aluminum cylinders with integral cooling fins and a fan which blows cooling air past the cylinders and interstage tubing. This type of cooling is sufficient for most low-pressure air compressors being operated in well ventilated spaces.

Most high-pressure and medium-pressure compressors aboard ships are cooled by sea water supplied from the ship's fire, flushing, or water service mains. The cooling water is generally available to each unit through at least two sources. Compressors located outside the larger machinery spaces are generally equipped with an attached circulating water pump as a standby source of cooling water.

The cooling water is circulated through the compressor in much the same manner as an automobile engine. The path of water in the cooling water system of a typical four-stage compressor is illustrated in figure 7-30. Not all systems have identical paths of water flow, but in all systems it is important that the coldest water be available for circulation through the system.

When an oil cooler is incorporated in the cooling system, valves are usually provided so that the water to the oil cooler can be controlled independently of the rest of the system. Thus, oil temperature may be controlled without harmfully affecting other parts of the compressor. Next in importance are the intercoolers and aftercoolers, then come the cylinder jackets and heads. The high-pressure air compressors require from 6 to 25 gallons of cooling water per minute, while medium-pressure air compressors require from 10 to 20 gallons per minute.

Since sea water is used as the cooling agent, all parts of the circulating system must be of corrosion-resisting materials. The cylinders and heads are therefore composed of gun metal or valve bronze composition, with water jackets

Figure 7-30.—Cooling water system in a typical multistage air compressor.

13010

cast integral with the cylinders. Each cylinder is fitted with a liner of special cast iron or steel to withstand the wear of the piston. The cylinder jackets are fitted with handholes and covers so that water spaces may be inspected and cleaned. Jumper lines are generally used to make water connections between the cylinders and heads, since these prevent any possibility of leakage into the compression spaces. In some compressors, however, the water passes directly though the joint between the cylinder and the head. With this latter type, extreme care must be taken to insure that the joint is properly sealed to prevent leakage which, if allowed to continue, would ruin both the cylinder liner and the piston.

The intercoolers and aftercoolers remove the heat generated during compression and cause the condensation of any vapor that may be present. This prevents unwanted accumulations at low points, water hammer, freezing or bursting of pipes in exposed locations, faulty operation of pneumatic tools and equipment, and possible damage to electric apparatus where air is used for cleaning. The removal of heat is also required for economical compression. During compression the temperature of the air is increased, thus causing the air to expand to a larger volume which, in turn, requires a corresponding increase of work to compress it. (The effect of changes in temperature on compressed gas is discussed in chapter 2.) Multistaging and cooling of the air between stages reduce the power requirement for a given capacity. The intercooling reduces the maximum temperature in each cylinder and thereby reduces the amount of heat which must be removed by the water jacket at the cylinder. Also, the resulting lower temperature in the cylinder insures good lubrication of the piston and the valves. Both the intercoolers and the aftercoolers are of the same general construction, except that the aftercoolers are designed to withstand a higher working pressure than the intercoolers.

Water-cooled intercoolers may be of the straight tube and shell type or, if size permits, may be of the coil type. In coolers with air pressure above 250 psi, the air flows through the tubes. Suitable baffles are provided in tubular coolers to deflect the air or water in its course through the cooler. In coil type coolers the air passes through the coil, with the water flowing around the outside.

Air-cooled intercoolers and aftercoolers may be of the radiator type or may consist of a bank of finned copper tubes located in the path of blast air provided by the air compressor.

Automatic temperature shutdown devices are fitted on all recent designs of high-pressure air compressors. Thus, if the cooling water temperature rises above a safe limit, the compressor will stop and will not restart automatically. Some compressors are fitted with a device that will shut down the compressor if the temperature of the air leaving any stage exceeds a preset value.

Compressor Assembly Components

As previously stated, certain other components are often considered as part of the compressor assembly. A brief description of these components is given in the following paragraphs. They are described in detail in other sections of this course, as indicated.

A filter and a moisture separator are incorporated in the line between the compressor and the receiver tank. Their purpose is to remove as much dirt and moisture as possible before the air enters the system. Filters and separators are discussed in chapter 6.

An air receiver or reservoir is installed in or near each space housing air compressors. The receiver acts as a supply tank and a storage tank for the pneumatic system. Air receivers are explained in chapter 6.

An unloading system that removes the compression load from the compressor while the unit is starting and automatically applies the load after the unit reaches operating speed is installed on most systems. Unloading valves are covered in more detail in chapter 10.

A pressure relief valve is installed in the assembly. It exhausts compressor discharge air to the atmosphere when the air pressure in the equipment being charged exceeds a predetermined maximum value. Pressure relief valves are described in chapter 10.

 1301131

CHAPTER 8

TYPES OF PACKING MATERIAL

One of the major problems that has always been present in fluid power systems is that of finding suitable packing materials for the various types of systems. These packing materials are commonly referred to as seals.

The seals used in fluid power systems and component units are of two general classes. One is the packing, which is used to provide a seal between two parts of a unit which move in relation to each other. The other class is the gasket, which is a seal between two stationary parts. This classification will apply in most cases; however, deviations may be found in some technical publications.

Seals are made from several different types of materials. The type of material used depends upon several factors. Pressure, temperature, type of fluid, and type of motion are a few of the factors that determine the type of material from which the seals must be made. Leather, synthetic rubber, natural rubber, cork, asbestos, Teflon, and metal are a few of the materials most commonly used. Synthetic rubber, cork, and leather seals are designed primarily for use with petroleum-base fluids; natural rubber seals are used with nonpetroleum-base fluids; and Teflon and metal seals may be used with either type of fluid. Asbestos material is used where heat is a problem.

The selection of the correct packings and gaskets and their proper installation are important factors in maintaining an efficient fluid power system. Manufacturers specify the type of packings and gaskets to be used in their equipment, and their instructions should be followed in replacing these items. If the proper part is not available, careful consideration should be given to the selection of a suitable substitute. The Bureau of Ships Technical Manual and other applicable technical manuals should be consulted if doubt exists in selecting the proper packing.

GASKETS

In selecting a gasket, the manufacturer has two major objectives. These objectives are to successfully prevent the escape of fluid and to prevent the entry of foreign matter into an assembly or component.

Effective seals are best obtained when the joint and the gasket are considered as a unit in the design stage. The best gasket will not seal a poorly designed joint, nor will a superbly engineered joint be sealed by a poor quality or improperly selected gasket.

To meet all the various sealing requirements, manufacturers have developed many types of gaskets. A few of the more common types are discussed in the following paragraphs.

NEOPRENE GASKETS

One of the materials most widely used in making gaskets for fluid power systems is neoprene (sometimes referred to as chloroprene), a synthetic rubber and fiber composition which comes in sheet form to be used between flat surfaces and in molded packing rings to be used around movable shafts and rods. Since neoprene is flexible, it is often used in sheet form at points where a gasket must expand enough to allow air to accumulate, as with cover plates on supply tanks, etc.

Over a period of time, oil tends to deteriorate the material used in making neoprene gaskets. For this or mechanical reasons, small particles of the material may be cast free in the system, and may restrict passage of the fluid. The condition of the gasket must therefore be checked whenever the unit is disassembled.

Since neoprene gasket material is soft and flexible, it may become misshapen, scratched, or torn. Great care is therefore necessary in working with neoprene gaskets. Shellac, gasket

130 DCI

sealing compounds, or "pipe dope" should never be used with sheet neoprene.

CORK GASKETS

The physical properties of cork composition gaskets make them among the most versatile and widely used gaskets. Cork gaskets have several features which make them ideally suited as a sealing material. A few of the more common properties are discussed in the following paragraphs.

The compressibility of cork composition gaskets makes them well suited for confined applications where no relief for side flow can be provided. The compressibility of the cork also makes a good seal which can be used under various pressures and allows the gasket to be cut to any desired thickness to fit any surface, while still forming an excellent seal.

Cork is generally recommended for use where sustained temperature at the gasket line does not exceed 275° F.

Cork requires the same care in disassembly as any other soft gasket material. The condition of the cork gasket should be checked for defects when a unit is disassembled, so that small particles will not be cast off into the system during use.

SYNTHETIC RUBBER GASKETS

The materials used in synthetic rubber gaskets are either of a neoprene or nitrile-butadiene base. These gaskets are available in wide ranges of density, tensile strength, and elongations.

Many factors contribute to make synthetic rubber gaskets ideal for seals. The elasticity of the material makes the use of the gaskets easier in many applications. Since synthetic rubber gaskets are virtually impermeable (prevent passage of fluid) in their uncompressed state, they require less sealing load than many other types of gaskets. Synthetic rubber gaskets are used in a wide variety of applications and are capable of functioning in temperature ranges as wide as -65° F to +300° F.

CORK AND RUBBER GASKETS

Cork and rubber gaskets are made by combining synthetic rubber and cork. This combination allows a sealing material which has the properties of either of the two materials. This means that gaskets can be made with the compressibility of cork, but with a resistance to fluids comparable to the specific synthetic rubber on which they are based. At the same time gaskets can also be made with the noncompressibility of rubber, but with many of the sealing properties of cork. This allows many variations in the designing of a suitable material for a seal.

Cork and rubber gaskets are generally recommended for use in the temperature range of -20° F to +275° F.

METAL GASKETS

One of the most common metal gaskets used in Navy equipment is the copper gasket. Therefore, copper gaskets are discussed in this chapter in lieu of other metal gaskets.

Copper gaskets are used extensively in naval ordnance systems, both in the form of flat copper rings used under adjusting screws, etc., to give oil seals, and as molded copper rings to be used with speed gears, etc., operating under high pressures. Either type is easily bent and requires careful handling. In addition, copper becomes hard when used over long periods or if subjected to compression. Whenever a unit or component is disassembled, the copper gasket rings should be replaced. However, if a new gasket is not available and the part must be repaired, then the gasket should be softened by annealing. (Annealing is the process of heating a metal, then cooling, so as to make the metal more pliable and less brittle.)

PACKINGS

Packings are made of synthetic or natural rubber, asbestos, plastics, hemp, flax, leather, lead, carbon, and other metallic substances. They are generally used as running seals; that is, in units that contain moving parts, such as actuating cylinders, pumps, valves, etc. Packings are made in the form of O-rings, Quad-rings, V-rings, and U-rings, each designed for a specific purpose. Figure 8-1 illustrates some of these packings. A section is cut out of each packing to show its cross-sectional shape. A few of the more common packings used in Navy equipment are discussed in the following paragraphs.

13013

O-RINGS

An O-ring, as shown in figure 8-1, is round in cross section. O-rings are made of resilient and elastic rubber or a synthetic rubber compound. All O-rings are molded and trimmed to extremely close tolerances in cross-sectional area, inside diameter, and outside diameter. The O-ring is generally fitted into a rectangular groove machined in the mechanism to be sealed.

O-ring seals are used for preventing both internal and external leakage. An O-ring seals by distortion of its resilient, elastic compound to fill the leakage path.

Figure 8-2 shows the proper installation of an O-ring seal. The clearance for the O-ring is less than its free outer diameter, and the O-ring is squeezed diametrically out-of-round even before the application of pressure (fig. 8-2 (A)).

When pressure is applied to the O-ring, the seal moves away from the pressure into the path of the leakage (fig. 8-2 (B)). The O-ring seal is designed so that the seal flows up to the passage, thus completely sealing it against leakage. The greater the pressure applied, the tighter the seal becomes. When the pressure is decreased, the resiliency and elasticity of the seal results in the O-ring returning to its natural shape.

Figure 8-1.—Packing rings.

O-ring seals have been used in aircraft hydraulic system components for several years and are now used in all types of fluid power systems.

Figure 8-3 shows a typical O-ring installation. Some of the precautions that must be observed at installation are discussed in the following paragraphs.

The first step in replacing an O-ring is to identify it both as to size and material. The size is indicated by a dash number, which always follows the part number of the O-ring. For example, in the part number MS28778-6, the -6 indicates the size.

After determining that the replacement seal is made of the correct material and is of the proper size, the seal should be inspected visually for cuts, nicks, or flaws and discarded if any defects appear. NOTE: More information on identification and inspection of O-rings is presented later in this section.

Prior to installation, the O-ring must be properly lubricated to insure good service life. The O-ring, grooves, and all surfaces over which the O-ring must slide should be lubricated with the fluid in which it will operate, if applicable; otherwise, petrolatum or other specified lubricant should be used.

O-rings will wear out very rapidly when they are not properly lubricated. In pneumatic systems, the O-rings must be coated with a lubricant which has a high melting point. Barium and lithium soap grease is recommended for use in low-pressure pneumatic systems, while a silicone lubricant is recommended for pneumatic systems which have pressures of 1,000 psi or more.

Another method of lubricating O-rings is to install felt washers on both sides of the O-ring. These washers will retain the lubricant for a fairly long time. Installations and fittings can also be provided so that the washers can be lubricated periodically.

When installing an O-ring, use extreme care to prevent scratching or cutting the seal on threads or sharp corners. Also make certain that it is not installed in a twisted condition, for it will not function correctly if twisted.

13014

Figure 8-2.—Properly installed O-ring.

To facilitate removing an O-ring seal, a special tool may be made of soft iron, aluminum, or brass rod. (See fig. 8-4.) Be sure that the edges are flattened and that the burrs and rough surfaces have been removed by polishing.

The O-ring seal, when used alone, is limited to systems having a maximum operating pressure of 1,500 psi or less. This is particularly true when it is used as a "running seal." In the event the seal is subjected to high pressure (3,000 psi, for example), it may become pinched. Figure 8-5 shows a set of O-ring seals being pinched because of high pressure. This condition may be prevented by using leather nonextrusion devices. By definition, an extrusion is a shape formed by passing material through a die. A nonextrusion device is commonly referred to as a "backup washer." Backup washers are discussed later in this chapter.

Figure 8-3.—Typical O-ring installation.

Identification and Inspection

Individuals working with fluid power systems must be able to positively identify, inspect, and install the correct size and type O-ring for every application in order to insure the best possible service.

The task of procuring and positively identifying the correct seal can be difficult since part numbers cannot be put directly on the seals. This situation is further confused by the fact that there is a continual introduction of new types of seals and the obsolescence of others.

Figure 8-4.—O-ring removal tool.

13015

TOXIN - a poison formed by an organism.

VASCULAR - pertaining to the tissues of plants that conduct fluids.

VECTOR - an agent that transmits disease.

VIRULENCE - relative strength or ability to cause disease.

VIRUS - a pathogenic entity which is not visible by any optical microscope.

WILT - a vascular disease which interferes with uptake of water and nutrients by a plant.

1299

Figure 8-5.—O-ring seals—pinched condition.

Because of the difficulties with color coding, O-rings are made available in individual hermetically sealed envelopes, labeled with all pertinent data. (See fig. 8-6.) It is recommended that they be procured and stocked in these envelopes.

When selecting an O-ring for installation, information printed on the envelope should be carefully observed. If an O-ring cannot be positively identified, it should be discarded.

The components from which O-rings are manufactured have been formulated for various operating conditions, temperatures, and fluids. An O-ring designed specifically as a static (stationary) seal will probably not do the job when installed on a moving part such as a hydraulic piston. Almost all kinds of O-rings are similar in appearance and texture, but their characteristics may differ widely. Here again the basic part number on the package label provides the most reliable identification.

Advances in fluid power systems have necessitated new O-ring compositions to meet changed operating conditions. O-rings were originally established for use in fluids at temperatures ranging from -65° F to +160° F. When new designs raised operating temperatures to a possible 275° F, more compounds were developed and perfected.

To identify O-rings, some manufacturers provide a color code. However, this is not a reliable or complete means of identification. There are several limitations to the color coding. Some coding is not permanent, while on others it may be omitted due to manufacturing difficulties or interference with operation. Furthermore, the color coding system provides no means to establish the age of the O-ring or its temperature limitations. When selecting an O-ring for installation, the basic part number on the sealed envelope provides the most reliable and complete identification.

Although an O-ring may appear perfect at first glance, slight surface flaws may exist. These are often capable of preventing satisfactory O-ring performance under the variable operating pressures of fluid power systems, and O-rings should be rejected for flaws that will affect their performance.

By rolling the ring on an inspection cone or dowel, the inner diameter surface can be checked for small cracks, particles of foreign material, and other irregularities that will cause leakage or shorten the life of O-rings. The slight stretching of the ring when it is rolled inside out will help to reveal some defects not otherwise visible. A further check of each O-ring should be made by stretching it between the fingers, but care must be taken not to exceed the elastic limits of the rubber. Following these inspection practices will prove to be a maintenance economy. It is far more desirable to take care identifying and inspecting O-rings than to repeatedly overhaul components because of faulty seals.

QUAD-RINGS

The Quad-ring is very similar to the O-ring discussed previously, the major difference being that the Quad-ring has a modified square type of cross section, as shown in figure 8-7. Quad-rings are molded and trimmed to extremely close tolerances in cross-sectional area, inside diameter, and outside diameter.

The Quad-ring is relatively new and is presently used as a packing for reciprocating or rotary motion and also as a static seal. The composition and design of Quad-rings are such that they could be used in most applications in place of O-rings. The relatively square cross section of the Quad-ring helps to eliminate the spiral twist that is encountered when an O-ring is used. The elimination of this spiral twist will in many instances extend the life of the seal.

Quad-rings are ideally suited for both low pressures and extremely high pressures. An example of a Quad-ring used as a cover gasket is depicted in figure 8-8.

Figure 8-6.—O-ring in sealed envelope as drawn from supply.

V-RINGS

A V-ring seal will provide a seal in only one direction. Therefore if a piston is to move in two directions under fluid pressure, two sets of V-rings must be used. V-rings are always installed with the open end of the V facing the pressure. Male and female adapters are used in conjunction with V-rings for reinforcement. (See fig. 8-9.)

Installation of the V-ring is slightly different from that of O-ring seals. The rings are placed in their respective grooves, one at a time. Make sure that they are seated properly; then tighten the adjusting nut (fig. 8-9). The adjusting nut should be tightened enough to hold the seals securely. If possible, the unit should be operated by hand to check the adjustment.

CUP PACKING

Cup packings are predominantly used as piston seals in fluid power systems. A cup packing is generally made of synthetic rubber

Figure 8-7.—A Quad-ring.

Figure 8-8.—Quad-ring used as a cover gasket.

or leather and is made, just as the name implies, in the shape of a cup. A typical cup packing is shown in figure 8-10.

U-RINGS

U-rings are used to prevent leakage in one direction only. Typical uses are in brake assemblies and brake master cylinders. U-rings are never used where high pressures will be encountered. As with the O-ring, when U-rings are used in pneumatic systems, provisions must be made to lubricate the packing. A typical U-ring is shown in figure 8-11.

FLANGE PACKINGS

Flange packings are recommended for use only in low-pressure applications. Flange packings are the least desirable of the previously mentioned types of packings. They are normally used only where there is not sufficient space for either a V-ring packing or a U-ring packing. Flange packings are sometimes referred to as "hat packings." A typical flange packing is shown in figure 8-12.

BACKUP WASHERS

One of the major problems in using seals is the problem of extrusion. Extrusion may be defined as distortion, under pressure, of portions of a seal into the clearance between mating metal parts. Figure 8-13 illustrates an extrusion of an O-ring. When pressure is applied, the seal will flow into the clearance. When the pressure is released, the O-ring returns to its original shape. However, the extrusion groove will appear as a cut beneath the surface of the ring. Eventually, the cut will become more severe and a section will be cut out of the O-ring. This will lead to the failure of the O-ring.

To eliminate extrusion, the manufacturer must use either harder seals, reduce clearance, or use backup washers as illustrated in figure 8-14.

A backup washer is a device normally used behind a seal to allow a higher pressure to be applied to the seal. A backup washer used behind an O-ring, for example, will extend the seal pressure from 1,500 psi to 3,000 psi.

When a part or component is disassembled and the packing is being replaced, the backup washers should also be thoroughly checked. Inspection of backup washers should include a check that surfaces are free from irregularities, that edges are clean-cut and sharp, and that scarf cuts are parallel.

The size of a backup washer is indicated by a dash number. The dash number of the backup washer should be the same as the dash number of the packing with which it is to be used.

Presently, backup washers are made of thin split metal, bakelite, chrome tanned leather, or Teflon. Teflon and leather are the most widely used. The material the backup washers are made of determines the shelf life limitations, and the manufacturers' recommendations, along with the standards established by the Navy, should normally be followed.

LEATHER BACKUP WASHERS

The chrome tanned leather backup washer is made of leather with hair on the outer side of the leather. The outer side of the leather is called the grain side while the cut or inside of the leather is called the flesh side. The backup washer is always installed in the gland (groove). The flesh side of the backup washer is always next to the gland. This positions the grain side to the seal. (In this case, the seal is an O-ring.)

13018

Figure 8-9.—V-ring installation.

If pressure is exerted on the seal in one direction only, place the backup washer away from the pressure. If pressure is applied alternately from both directions, one backup washer must be placed on each side of the O-ring.

NOTE: Leather backup washers should never be cut, as results have shown that when pressure is applied, this will be the section most likely to fail.

TEFLON WASHERS

Backup washers made of Teflon do not deteriorate with age, are unaffected by any system fluid or vapor, and tolerate temperature extremes in excess of those encountered in high-pressure fluid power systems. They are procurable under a number of basic part numbers and are normally interchangeable; that is, any Teflon backup washer may be used to replace any other Teflon backup washer if it is of proper overall dimension to support the applicable packing.

NOTE: In checking the Teflon spiral backup washers, make sure that the coils do not separate more than one-fourth inch when unrestrained.

Figure 8-10.—Typical cup packing.

INSTALLATION

Unfortunately, the length of time that a seal will function properly depends on many factors; many of them unpredictable. Therefore, it is almost impossible to say that a seal will wear out in a specified time.

Figure 8-11.—Typical U-ring.

13019

Figure 8-12.—Flange packing.

Figure 8-13.—Extrusion of an O-ring.

Each time a component or unit is disassembled the seals should be carefully inspected. If there is any doubt as to their condition, they should be replaced. In most cases, automatic replacement of the seal is standard procedure. The manufacturers' recommendations along with the previous experience of the personnel repairing the unit or component should be the main criteria for determining when to replace a specific seal. Installation of seals should be carried out as specified in the Maintenance Instructions Manual, manufacturers' publication, or the Bureau of Ships Technical Manual.

Figure 8-14.—O-ring with backup washers.

PACKING SHELF LIFE

Packing shelf life goes hand in hand with inventories. It has been found with experience that packings deteriorate with age. Therefore, knowing and understanding packing shelf life will save many hours of unnecessary toil experienced in repacking a unit and having it still leak because the packing was defective due to age.

Prior to the installation of natural and synthetic rubber packings, a check must be made to determine whether these parts are acceptable for use. All natural and synthetic rubber packing containers are marked to facilitate an age control program. This information is available for all packings used, regardless of whether the packing is stocked on shipboard at stock distribution points, or furnished as an integral part of a component. Positive identification, indicating the source, "cure date," and "expiration date" must be made of packings.

The age control of all natural packings is based upon the cure date stamped on the manufacturer's unit package, intermediate package, and shipping container. Shelf life control of all packings is governed by the expiration date stamped beside the manufacturer's cure date on each package.

Expiration date is the date after which a packing CANNOT be used in service, and time of delivery means the date of acceptance by the purchaser. All packing is scrapped if not put into use by the time of the expiration date.

Cure date means the time the packing was manufactured and is designated by the quarter of the year and the year of manufacture. Packings manufactured during any given quarter are considered one-quarter old at the end of the succeeding quarter. For purposes of explaining the coding used by manufacturers to designate the cure date, each year is divided into quarters as follows:

1. First Quarter: January, February, and March.
2. Second Quarter: April, May, and June.
3. Third Quarter: July, August and September.

13029

4. Fourth Quarter: October, November, and December.

Tables 8-1 and 8-2 establish shelf life limitations of natural and synthetic rubber for Supply Points and Repair Activities and Fleet Service Vessels.

In order to maintain components in an RFI (ready for issue) state, all packing assembled in a component must be removed and scrapped on its expiration date. The component must then be reassembled with new packing, not to exceed 4 quarters (1 year) in age. After repacking, the component must be redated to show the expiration date of the packing just installed. It should be returned to storage until it is required for service, or reexamination, whichever occurs first.

To identify the age of natural or synthetic rubber packing, use the following procedure:

1. On the manufacturer's containers, stamp the cure date by quarter of the year and the year in accordance with Specification MIL-STD-129. The quarter of the year should be separated by the letter "Q" to indicate whether first, second, third, or fourth quarter. Containers of packings from manufacturers marked with an illegible cure date are cause for rejection of delivery.

2. An expiration date should also appear on the manufacturer's unit package to facilitate scrapping. The date should be specified by month and year, 2 years after the manufacturer's cure date, using the last month of the quarter.

EXAMPLE: 1Q66 Expiration Date: March 1968.

1Q66 means a cure date of the first quarter of the calendar year 1966. Expiration Date: March 1968 indicates the time when the usefulness of the packing expires.

Table 8-1.—Supply points and repair activities.

From: Cure Date	Maximum age in quarters
To: (1) Time of Delivery from manufacturer or his agent.	2 (6 months)
(2) Time of Delivery from source other than manufacturer or his agent.	4 (1 year)
(3) Time limit of shelf storage.	8 (2 years)

Table 8-2.—Fleet service vessels.

From: Cure Date for Service Installation	Maximum age in quarters
To: (1) Time of Installation for service use on equipment.	8 (2 years)
(2) Time for Replacement of packing in stored equipment.	8 (2 years)

13021

Natural or synthetic rubber packing must not be removed from the manufacturer's unit package until ready for use, and should be stored in an area protected from sunlight and drafts. The storage temperatures, also applicable to components in which these packings are installed, should normally range from 60° F to 100° F, and must not exceed 125° F.

13022

CHAPTER 9

CONTROL AND MEASUREMENT OF FLOW

It is all but impossible to develop a practical fluid power system without using valves, as it is equally difficult to manage a fluid power system without knowing how to control its valves and insure their efficient operation. The first part of this chapter includes a brief introduction and classification of the different valves used in fluid power systems. This is followed by detailed descriptions of those valves which control fluid flow.

Some fluid power systems require devices for measuring the quantity or rate of flow through the system. The latter part of this chapter is devoted to various types of flowmeters used for measuring flow.

INTRODUCTION TO VALVES

A valve is defined as any device by which the flow of fluid may be started, stopped, or regulated by a movable part which opens or obstructs passage. As applied to fluid power systems, valves are used for controlling the flow of the fluid, the pressure of the fluid, or the direction of the fluid flow. Fluid power system valves may be controlled manually, electrically, pneumatically, mechanically, hydraulically, or by combinations of two or more of these means.

Valves must be accurate in the control of fluid pressure and flow. Usually, no packing is used between the valving element and the valve seat since fluid leakage is reduced to a negligible quantity by precision machined surfaces, resulting in carefully controlled clearances. (Packing is required around valve stems, between lands of spool valves, etc.) This is another very important reason for using only the recommended fluid in the system and for keeping the fluid clean. Oxidation, rust particles, and other foreign materials such as dust, dirt, lint, etc., can cause considerable damage to precision valves. This contamination will cause valves to stick, may plug small orifices, or cause abrasion of the valving surfaces resulting in leakage through the valve. Any one of these can result in inefficient operation or complete stoppage of the equipment.

CLASSIFICATION OF VALVES

All the types of valves available for fluid power systems are too numerous to mention in this course. Most valves, however, are variations of three fundamental classes described in the following paragraphs.

Valves are sometimes classified as simple, compound, or direction valves, according to their method of operation. A simple valve requires only a single internal motion for its operation. Fluid acting on one side of the valve, for example, opens it against the resistance of gravity or a spring; or the valve is opened and closed manually by turning a screw so that a passage for the fluid is opened or closed. A compound valve involves a combination of internal motions for its operation. Directional valves are used to control the direction of flow of fluids along two or more paths.

As a general rule, simple valves include those which control the flow of fluid; while compound valves include those which control the pressure. Flow control valves are described in this chapter. Pressure control valves are discussed in chapter 10, while directional valves are described in chapter 11.

APPLICATIONS

Each type of valve used in fluid power systems has a specific purpose or, in some applications, a combination of different purposes. These applications and purposes are discussed in more detail as the different valves are described in this chapter and in chapters 10 and

13023

11. In general, however, the applications of valves according to their classifications, are briefly covered in the following paragraphs.

Flow control valves are used in fluid power systems to open and close a line to flow or to control the rate of flow through the lines. They are sometimes used as ON and OFF valves to isolate circuits of the system during certain operations.

The uses of pressure control valves include the regulation of system pressure, the protection of the system and components from pressure overload, and the control of the sequence of operation of certain components in some systems.

Among other applications, directional control valves are used to control the path of the fluid to operating components. For example, these valves are used to control the direction of rotation of actuating motors, and the direction of movement of actuating cylinders.

FLOW CONTROL VALVES

A typical example of a valve used to control flow is the ordinary water faucet. It is normally in the closed position allowing no flow. It can be fully opened allowing a full flow. The rate of flow is varied by turning the faucet handle clockwise or counterclockwise which changes the size of the opening of the faucet. Many of the flow control valves used in fluid power systems are similar in design and operation to the water faucet. Some of the different types of flow control valves used in fluid power systems are described in the following paragraphs.

PLUG VALVES

A plug valve, sometimes referred to as a cock, consists of a hollow cylindrical body into which is fitted a tapered cylindrical plug. Figure 9-1 is an exploded view of a plug valve, including a cross sectional view of the body. The top of the plug extends up through the gland, and can be turned with a wrench. In many plug valves, the plug terminates in a handle for manual control of the valve.

The body of the valve is permanently fixed in the line with holes or ports in the wall of the cylindrical body aligned with the flow of the fluid through the line. The plug, which also contains holes or ports, fits snugly into the valve body. When the plug is open the ports of the plug are in line with the ports of the body and allows the fluid to flow through the valve. (See fig. 9-2.) Flow is stopped by a quarter turn of the plug, which aligns the solid areas of the plug with the ports in the body. The handle of the plug is marked by some method to indicate whether the valve is open or closed.

Although the inside surfaces of plug valves are machined to give close contact, the meeting of metal with metal offers dangers of seizing. When plug valves stand normally in an open position the parts of the plug which provide the seal are not directly in contact with the fluid;

Figure 9-1.—Plug valve.

Figure 9-2.—Operation of the plug valve.

USCI
CS28024

but when the valve is normally closed the fluid will act on one of the sealing surfaces. Under ordinary conditions, however, plug valves can be easily opened or closed.

Plug valves are used as fully ON or fully OFF valves. They are not designed to be used in a semiopen position; that is, to throttle or vary the volume of flow. This is especially true if grooves in the wall of the body are filled with packing to separate metal from metal. In a partly open position, this packing would eventually wear away. In any event, unequal wear is encouraged if the valve remains in the partly open position. Small plug valves are sometimes used in systems containing liquids to free the system of accumulated air. The valve is opened so that the air can escape. When the liquid begins to flow continuously the valve is closed.

GATE VALVES

In this type of valve, flow is controlled by means of a wedge or gate, which can be moved up and down across the line of flow by a handwheel, to open and close the passage. The principal elements of this type valve are shown in cross section in figure 9-3. Part (A) shows the line connection and the outside structure of the valve; while (B) shows the wedge or gate inside the valve and the stem to which the gate and the handwheel are attached. When the valve is open, the gate stands up inside the bonnet, its bottom flush with the wall of the line. While the valve is closed, the gate blocks flow by standing straight across the line, where it rests firmly against two seats extending completely around the line.

Gate valves permit straight flow and offer little or no resistance to the flow of fluid when the valve is completely open. Although they are sometimes placed in the partly open position to restrict the rate of flow, gate valves are intended for use as fully open or fully closed valves. If the valve is left partly open, the face of the valve stands in the flow of fluid. This flow of fluid will act on the face of the valve causing it to erode.

Two different types of gates are used in the construction of gate valves. One type is a solid or hollow wedge. This type is satisfactory for small valves in low pressure systems. However, wedges are sometimes difficult to tighten and will leak when slightly worn. The other type consists

Figure 9-3.—Cross sectional view of a gate valve.

of two facing discs. By using discs a better closure is provided, since the discs are forced apart, snug against the valve seats, as they are moved into position. One arrangement for accomplishing this is shown in figure 9-4. One of the two facing discs, composing the valve, has been removed to show how the valve is constructed. Two cams with arms extending outward stand opposite each other on slanting surfaces in the space between the discs. As the discs move into the closed position the arm of each cam engages a lug on the body of the valve and is turned on the slanting cam bearing surface, forcing the discs against the valve gates during closure.

Gate valves are available in different types of stem connections. Figure 9-5 illustrates three different types. In figure 9-5(A), the stem screws down into the valve gate as the valve is opened. In this type the stem does not rise or fall outside the body of the valve as the valve is opened or closed. In figure 9-5(B), the stem

Figure 9-4.—Operation of gate valve.

rises outside the valve as the valve is opened, but the stem screw operates inside the body of the valve. In figure 9-5(C), the stem screw operates at the level of the handwheel, so that the stem rises independently of the wheel as the valve is opened. This is called the outside-screw-and-yoke type valve.

Valves with rising stems are used when it is important to know by immediate inspection whether a valve is open or closed. The non-rising stem type is least likely to leak, and requires less space. Gate valves are difficult to open or close if the pressure is high. Open and close valves slowly. Do not force the disc against the seat. If a valve fails to seat properly, open it slightly so that the sediment on the seat will flush away. If it still fails to seat, the system must be shut down and the valve disassembled to locate and correct the trouble.

GLOBE VALVES

Globe valves derive their name from their body shape. (It should be noted, however, that other types of valves may also have globular bodies; hence, the name may tend to be misleading.)

The controlling member of the globe valve, called the disc, is screwed directly on the end of the stem. The valve is closed by lowering the disc into the valve seat. Since the fluid flows equally on all sides of the center of support when the valve is open, there is no unbalanced

Figure 9-5.—Types of gate valves.

613026

Figure 9-6.—Operation of a globe valve.

pressure on the disc to cause uneven wear. The operation of the globe valve is illustrated in figure 9-6.

The moving parts of a globe valve consist of a disc, valve stem, and a handwheel. Figure 9-7 (A) is an exploded view of a globe valve. The stem, which connects the handwheel and the disc, is threaded and fits into the threads in the valve bonnet. Discs are available in various designs. (See fig. 9-7 (B).)

When the valve is closed, the valve disc rests against the port, which is referred to as the valve seat. The edge of the disc and the seat are very accurately machined so that they form a tight seal when the valve is in the closed position. When the valve is open, the fluid flows through the space between the edge of the disc and the seat. The rate at which the fluid flows through the valve is regulated by the position of the disc. The valve must always be installed *with the pressure* against the face of the disc.

Although globe valves are sometimes used to throttle (vary) the rate of flow, they are most commonly used as fully open or fully closed valves.

NEEDLE VALVES

Needle valves are similar in design and operation to globe valves. Instead of a disc, a needle valve has a long tapered point at the end of the valve stem. Figure 9-8 is a sectional view of a needle valve. The long taper permits the needle valve to be opened or closed gradually. Needle valves are used to control flow into delicate gages which might be damaged if fluid under pressure were suddenly delivered to them. Needle valves are also used to control end operation of a work cycle, where it is desirable that a work motion be brought slowly to a halt; and at other points where precise adjustments of flow are necessary and where a small rate of flow is desired.

Figure 9-7.—Globe valve with various types of discs.

93043027

Although many of the needle valves are of the manually operated type illustrated in figure 9-8, modifications of this valve are often used as variable restrictors, described in the next section.

RESTRICTORS

Restrictors, sometimes referred to as orifices, are used in fluid power systems to limit the speed of movement of certain actuating devices. They do so by serving as restrictions in the line, thereby limiting the rate of flow. Figure 9-9 shows an example of a typical restrictor. This type is referred to as a fixed restrictor.

Some types of restrictors are constructed so that the amount of restriction can be varied. One type of variable restrictor is illustrated in figure 9-10. This type is simply a modification of the needle valve previously described. Instead of a handwheel control, this valve is constructed so that it can be preadjusted to alter the time of operation of a particular subsystem. It can be adjusted to conform to the requirements of a particular system. This permits the same type valve to be used in different systems.

Figure 9-8.—Sectional view of needle valve.

Figure 9-9.—Fixed restrictor.

ORIFICE CHECK VALVES

Check valves are described in more detail in chapter 11, since their purpose is to control the direction of flow. However, they are used in conjunction with some types of flow control valves. The orifice check valve is an example, and is used in fluid power systems to allow normal speed of operation in one direction and a limited speed in the other. Some typical examples of orifice check valves are illustrated in figure 9-11.

Figure 9-11 (A) illustrates a cone-type orifice check valve. The cone (2) is moved off its seat whenever sufficient fluid pressure is applied at port (4), thus allowing free flow of fluid through the valve. Flow through the valve in the opposite direction is restricted by the size of the orifice (3) located in the center of the cone. Figure 9-11 (B) shows a ball-type orifice check valve. Fluid flow through the valve from left to right is normal, whereas fluid flow through the valve in the opposite direction is restricted by the size of the orifice (5) located in the housing of the valve.

An orifice check valve is often installed in the alternating line that carries fluid from the actuating device (for example, an actuating cylinder) as it is operated in the direction in which slower movement is desired. (The line which delivers fluid under pressure to the actuating device for one direction of operation becomes the line which carries the return flow from the actuating device during the opposite direction of operation. Hence, the term alternating line.) This causes the piston speed to be retarded, since fluid cannot escape from the other end of the cylinder any faster than the orifice will allow the fluid to enter the return line.

This type valve is frequently used in aircraft hydraulic systems in the subsystem which

Figure 9-10.—Variable restrictor.

Figure 9-11.—Orifice check valves.

retracts and extends the landing gear. The orifice check valve is installed in the UP line (pressure line for the retraction of the landing gear) and allows the fluid to flow freely into the cylinder for rapid retraction of the landing gear. As the gear is extended, fluid leaving the cylinder returns through the UP line and must pass through the orifice. Thus, a cushioning effect results and the gear falls slowly, thereby preventing structural damage. If the restriction were placed in the DOWN line, it would limit the quantity of fluid entering the cylinder and have no effect on the fluid leaving. This would not correct the situation because the heavy gear tends to fall freely, causing a partial vacuum in the cylinder. This would cause the gear to fall too rapidly, resulting in structural damage to the aircraft.

Circuits in which the flow is restricted as the fluid leaves the actuating device, such as the landing gear circuit just described, are often referred to as meter-out circuits. The fluid is metered out of the actuating device. Some circuits require the flow of fluid to be controlled as it enters the actuating device. These circuits are referred to as meter-in circuits.

COMPENSATED VALVES

The flow control valves previously discussed in the chapter are not compensated for changes in fluid temperature or pressure, and are referred to as noncompensating valves. The rate of flow through these valves can vary at a fixed setting if either the pressure or temperature of the fluid changes. Viscosity (discussed in chapter 3) changes, which are often the result of temperature changes, can also cause flow variations through a valve. These valves are satisfactory for use in fluid power systems where slight variations of flow are not a critical factor to be considered. However, some systems require extremely accurate control of the actuating device. Compensated flow control valves are used for this purpose. They automatically change the valve adjustment or pressure drop across the restriction to provide a constant flow at a given setting.

Figure 9-12 illustrates an example of a compensated flow control valve. This type valve meters a constant flow regardless of variation in system pressure. Although it is usually used to meter fluid into a circuit, it can be used to meter fluid as it leaves the circuit. Flow

control, flow regulator, and constant flow valve are all terms used to describe this valve. In this course it is referred to as a flow regulator.

The flow regulator has only one moving part, the piston (5), as illustrated in figure 9-12. The valve will regulate flow from left to right only, since this type flow regulator controls the rate of flow in only one direction. The body of the valve is marked with an arrow to indicate the direction of regulated flow.

Operation of the flow regulator can be seen in figure 9-12. Figure 9-12 (A) shows the valve in the free flow condition. Fluid enters port (3), passes through the orifice in the head of piston (5), through slots (2) in the side of piston (5), and out port (6). If fluid tries to increase its flow through the orifice in the head of the piston, there is more resistance and a greater pressure differential between the fluid entering the orifice and the fluid leaving it. This pressure differential, caused by a momentary increase in flow, causes the piston to move to the right and compresses the spring. When the piston moves to the right, the slots (2) in the piston no longer line up with the holes in the regulator body (fig. 9-12 (B)), and an additional restriction is placed on the fluid which decreases the rate of flow. The piston cannot move to the right far enough to completely block the ports in the side of the regulator body because the pressure on the right side of the piston will build up to a value equal to the pressure in port (3) and against the left side of the piston.

An increase of pressure normally increases fluid flow through an orifice, but this is not the case with the flow regulator. As the pressure increases, the size of the orifice or opening for the fluid decreases, thus maintaining a constant flow. If the resistance to movement of the actuating unit decreases, the fluid flow starts to increase. An increase of fluid flow to the actuating unit causes a decrease in pressure against the piston (5), allowing the piston to move to the right and thereby decreasing the size of the slot opening (2). This allows less fluid to flow to the actuating unit. Thus, the flow regulator maintains a constant rate of flow regardless of variations in system pressure and regardless of the resistance to movement of the actuating unit.

An example of a typical flow regulator installation is shown in figure 9-13. This installation provides for the fluid to be metered

1. Body.
2. Slots.
3. Input port.
4. Retainer.
5. Piston.
6. Output port.

Figure 9-12.—Flow regulator.

into the circuit. System pressure enters port (5). When the directional control valve (3) is positioned, fluid flows through the flow regulator (4). Thus, regardless of the direction of movement of the actuating cylinder (1), one of the alternating lines (2) will have regulated flow through it, insuring a smooth operation of the actuator. These valves are available in different flow capacities, and are rated in gallons per minute (gpm). This type of compensated valve is nonadjustable. Adjustable valves are required and are available for some fluid power systems.

FLOW EQUALIZER

Flow equalizers (flow dividers) are used in some hydraulic systems to synchronize the operation of two actuating units. To do this, it divides a single stream of fluid from the directional control valve into two equal streams. Thus, each actuating unit receives the same rate of flow, and both move in unison. During operation in the opposite direction, the flow

18030

equalizer combines the two streams of return fluid at an equal rate. Therefore, the flow equalizer synchronizes the movement of the actuating units during both directions of operation. Since the unit equally divides the combined flow, it is said to be dual acting.

One type of flow equalizer is illustrated in figure 9-14. Figure 9-14 (A) shows the valve in the splitting (divided flow) position. Fluid under pressure from the directional control valve enters port (3). This pressure overcomes spring tension and forces the plug (4) down and uncovers the two orifices in the sleeve (2). The fluid then splits and tends to flow equally through the two side passages (1) and (5). The fluid flows through the two splitting checks valves (7) and (15), through the metering grooves (10) and (14), through ports (9) and (13), and through the connecting lines to the actuating cylinders. Any difference in the rate of flow between the two passages results in a pressure differential between these two passages. Then the free-floating metering piston (11) shifts to equalize the internal pressure, and the flow equalizes.

To illustrate this equalizing action, assume that the actuating unit attached to a line from port (9) meets less resistance than the one attached to a line from port (13). The rate of flow through port (9) tends to increase, but in doing so, the flow also increases through passage (5). Fluid leaving port (13) meets with more resistance; so the flow through passage (1) decreases, and the pressure becomes greater than the pressure in passage (5). This momentary pressure differential forces the free-floating metering piston (11) to the left. This causes the space between the piston land (8) and the metering groove (10) to become smaller, which restricts the flow of fluid out of port (9). Thus, the flow equalizer imposes a restriction on the fluid that has a tendency to increase in rate of flow, and the two streams equalize.

1. Actuating cylinder.
2. Alternating lines.
3. Directional control valve.
4. Flow regulator.
5. Pressure line.
6. Return line.

Figure 9-13.—Flow regulator installation.

The combining position of the flow equalizer is illustrated in figure 9-14 (B). This shows the unit joining the two streams of fluid as it flows from the actuating units. Here, the fluid enters ports (9) and (13) of the valve. The fluid cannot flow through the splitting check valves. Therefore, it takes the path of least resistance, which is around the cylindrical shaped metering piston, and enters the combining check valves (6) and (16) as indicated by the arrows. The pressure of the fluid opens the check valves and then the fluid flows through passages (1) and (5) to the orifice sleeve (2). The fluid pressure will then force the orifice sleeve upward, which opens the orifices and allows the fluid to flow out port (3).

Again for purposes of illustration, assume that the actuating unit attached to a line from port (9) moves with less resistance than the unit attached to a line from port (13). Fluid entering port (9) attempts to flow faster, but as it leaves the check valve and flows up passageway (5) it is restricted by the orifice. Therefore, if the flow momentarily increases, the orifice will cause an increase in pressure in passage (5), which forces the metering piston (11) to the right. This results in a restriction between the metering groove (10) and the piston land (8), and the stream of fluid which tends to flow at a greater rate is restricted and equalizes with the other stream.

PRIORITY VALVES

In systems with two or more circuits, it is sometimes necessary to have some means of supplying all available fluid to one particular circuit in case of a pressure drop in the system. A priority valve is often incorporated in the system to insure a supply of fluid to the critical circuit. The components of the system are arranged so that the fluid to operate each circuit, except the one critical circuit, must pass through the priority valve.

13031

One type of priority valve is illustrated in figure 9-15. Figure 9-15 (A) shows the valve in the priority flow position. Fluid passes around the poppet and forces the piston to the right which compresses the piston spring. The poppet follows the piston and keeps the valve closed until the preset pressure is reached. (NOTE: The preset pressure depends on the requirements of the system and is set by the manufacturer. For example, assume that the critical system requires 1,500 psi for efficient operation.) When the pressure reaches 1,500 psi, the poppet reaches the end of its travel. As the pressure increases, the piston continues to move to the right, which unseats the poppet and allows a flow through the valve. If the pressure drops below 1,500 psi, the compressed spring moves the piston to the left, the poppet seats, and flow through the valve stops.

Figure 9-15 (B) shows the priority valve in the free flow position. The flow of fluid moves the poppet to the left, the poppet spring compresses, and the poppet unseats. This allows free flow of fluid through the valve.

FLOWMETERS

Although flowmeters are normally associated with systems in which fluids are consumed, such as fuel oil, gasoline, water, etc., they are sometimes required in fluid power systems. Flowmeters are incorporated in test stands which are used to test and adjust fluid power systems and/or components. For example, pumps are rated in gallons per minute (chapter 7) and can be tested for their rated capacity by the use of a test stand which has a flowmeter incorporated.

Measurement of flow may be expressed in units of rate, such as gallons per minute, pounds per hour, cubic feet per second, or in terms of total quantity, such as gallons, pounds, or cubic feet. (This is similar to the speedometer of an automobile. The needle indicates the speed of the automobile in miles per hour which compares with the rate-of-flow type flowmeter. The other indicator, called the odometer, indicates total miles and compares to the quantity type flowmeter.)

A reciprocating pump which displaces a uniform volume of fluid for each stroke of its piston could be used as a meter by installing a device for counting the piston strokes. But the pump would have to be designed to minimize leakage and guarantee uniform displacement. Measurement of flow is accomplished by a variety of means, depending upon the quantities, flow rates, and types of fluid involved. All fluid meters are made to measure fluids of definite specific gravities and characteristics, and must be used only for the purpose for which they were made. Each meter is tested and calibrated before it is shipped from the factory. Several types of flowmeters are described in the following paragraphs.

NUTATING PISTON DISC FLOWMETER

In this type flowmeter the fluid passes through a fixed volume measuring chamber divided into upper and lower compartments by a disc. During operation, one or the other compartment is continually being filled while the other is being emptied. As it passes through these compartments, the pressure of the fluid causes the disc to roll around in the chamber, in a

Figure 9-15.—Priority valve.

manner described later, and its movements operate a counter, through suitable gearing, to indicate the volume of fluid passed through the meter. The counter somewhat resembles the odometer of an automobile, previously mentioned, except that the flowmeter usually registers in gallons.

The heart of the meter is the measuring chamber and the disc piston. Figures 9-16 (A) and (B) show how the disc is located in the measuring chamber. Figure 9-16 (C) is a sectional view illustrating one-half of the measuring chamber. It is bound at the top and bottom by conical surfaces (1) and (2), which are joined at their outer edges by spherical surface (3). A sectional view of the entire meter is illustrated in figure 9-17.

Referring to figures 9-16 (A) and (B), the upper and lower surfaces of the chamber converge towards the center to form a spherical cavity for the ball (4), through which passes the spindle (5), which is connected with the counting gears (fig. 9-17). Disc (6) is attached to the ball. Both the ball and disc are machined to fit closely in the chamber. There is a slot (8) in the disc at one point, through which passes the thin partition (7) which cuts the chamber in two. There are openings in the outer wall of the chamber on each side of the partition. Opening (9) is the fluid inlet, while opening (10) is the outlet.

When the ball carrying the disc and the spindle is tilted as far as it can go, the bottom of the disc makes a close contact with the bottom conical surface of the chamber, while the top of the disc similarly contacts the upper conical surface of the opposite end of the disc. Since the disc is flat while the contacting surfaces are conical, contact takes place along a straight line on each surface. The lines of contact produce seals, which when taken in connection with the partition (7), divide both the upper and lower compartments into two parts. The net effect is that the disc and partition produce four separate compartments in the measuring chamber, two above the disc and two below. The top and bottom compartments are separated from each other by the disc, while the pairs of compartments respectively above and below the disc are separated by the seal formed at the line of contact between the disc and the conical top and bottom surfaces, and also by the partition.

Spindle (5) rises from ball (4) and passes through wheel (11) at a point near its outside edge. Vertical shaft (12) is attached to wheel (11) and rotates with it. This shaft is connected at its upper end to the measuring gears, and is mounted directly over ball (4). When wheel (11) turns on its axis, the position of the shaft keeps the spindle inclined at just the angle to produce a continuous seal between disc (6) and the upper and lower surfaces of the measuring chamber.

For the purpose of simplicity, consider the meter as a pump driven by some outside force. The action of the meter can be understood by imagining wheel (11) to be revolved by means of shaft (12). The spindle would revolve with it, and would trace a conical path in space, as shown in figure 9-18. This movement of the spindle would control the positioning of the disc. When the spindle is in position (A), for example, the disc would also be in position (A), while the positions (B) and (C) for the spindle and disc would also correspond.

The disc cannot rotate, because partition (7) stands in slot (8). The disc, therefore, wobbles up and down (nutates), while the seal lines, formed by the disc and the top and bottom walls of the measuring chambers, are made to revolve around the chamber.

For simplicity, consider only the lower partion of the chamber. The seal will always belong the line which has the greatest inclination. As this seal line moves in the direction shown by the arrows in figure 9-17, it will sweep the fluid before it and cause it to be discharged through the opening (10). At the same time it will be opening up an increasing volume in the compartment behind the moving line of the seal. Since this space is open to the inlet (9), it is filled with fresh fluid. When the line of seal passes the partition (7), all the liquid formerly

in front of the seal will have been forced out of the discharge. The seal line then starts to push the fluid, which was formerly behind it, forward. The line of flow of the fluid is as shown in figure 9-17.

Obviously, if the wheel (11) were continuously rotated, the disc (6), would move a volume of fluid equal to the volume of the lower half of the chamber from the inlet to the outlet, for every rotation. During this same revolution the top section is doing the same, except that its seal is always directly opposite the lower seal in the measuring chamber. Therefore, for every revolution, the piston will displace the volume of the entire chamber just once.

In the previous discussion, the meter is described as though it were a pump operated by the rotation of wheel (11). Actually the operation of the meter is just the reverse. It is operated by the slightly greater fluid pressure at the inlet as compared with the outlet. This pressure differential causes the seal line to advance around the measuring chamber, and in doing so it rotates wheel (11). This in turn revolves the indicating register of the meter by means of shaft (12) and suitable reduction gearing.

Standard meters of this type are suitable for temperatures to 200° F, and for pressures to 150 psi, although models are available for higher

13036

Figure 9-18.—Operation of disc and spindle of nutating piston disc flowmeter.

temperatures and pressure. The meters are accurate to about 1 percent or less. The accuracy of the meter is not affected by pressure variations.

PROPELLER TYPE FLOWMETER

Figure 9-19 illustrates a propeller type flowmeter. The propeller is located in the line of flow and is connected by suitable gearing to the indicator or counter. The propeller rotates at a speed relative to the velocity of the flow through the line. The revolutions are registered through the gearing to the counter, the rate of rotation being volume rate of flow. This type meter is calibrated by the manufacturer for a specific fluid. The accuracy of this meter depends, to varying degrees, on the temperature, pressure, and characteristics of the fluid.

TURBINE TYPE FLOWMETER

The turbine type flowmeter is similar to the propeller type just described. Figure 9-20 illustrates an installation of a turbine type flowmeter. The fluid flows through the helical (spiral) impeller. The flow causes the impeller to rotate. The impeller is connected through suitable gearing to the counter. The revolutions of the impeller, which changes as the velocity of the flow changes, are counted through the gearing to the counter. The rate of rotation of the impeller indicates the volume flow rate. Like the propeller type flowmeter, the accuracy depends on the temperature, pressure, and characteristics of the fluid. This type flowmeter is calibrated by the manufacturer for a specific type fluid.

ROTAMETER

The rotameter is a device for measuring the rate of flow of a fluid. Figure 9-21 illustrates the operation of a rotameter.

The rotameter is an upright glass tube through which the fluid flows. A metal casing with a Plexiglas window protects the glass tube. The tube is tapered, with the small end at the bottom. Inside, a small metal rotor with a central hole slides up and down on a guide rod, and is caused to spin for free sliding by small vanes cut in its sides. Since the tube is tapered, the space between the rotor and the tube wall

Figure 9-19.—Propeller type flowmeter.

Figure 9-20.—Turbine type flowmeter.

13037

Figure 9-21.—Rotameter.

13038

increases as the rotor rises, permitting more fluid to flow through that space. Therefore, the rotor always rises to a height corresponding to the rate of flow at any particular time. A scale on the tube is calibrated to indicate the rate of flow in the desired measurement—gallons per hour, gallons per minute, pounds per hour, etc.

13089

CHAPTER 10

MEASUREMENT AND CONTROL OF PRESSURE

In any fluid power system a means must be provided for measuring the pressure in the system. Likewise, a means must be provided for controlling this pressure. In fluid power systems the pressure is measured by various types of pressure gages and is controlled by various types of valves, pressure regulators, pressure switches, or similar mechanisms.

In the first part of this chapter, the various types of pressure gages commonly used in fluid power systems are described. The latter part of the chapter is devoted to the valves and other units commonly used in controlling pressure.

PRESSURE GAGES

Pressure gages are used in fluid power systems to measure pressure so that the operators of fluid power equipment can maintain pressures at safe and efficient operating levels. Any excess or deficiency of pressure should be immediately investigated with a view of locating and removing the cause of the trouble.

Pressure is generally measured in pounds per square inch, as discussed in chapter 2. Gages used in fluid power systems are therefore calibrated in pounds per square inch (psi). Gage readings indicate the fluid pressure set up by the opposition of forces within the system. Atmospheric pressure also acts on the system, but it can be ignored in practical operation because its action at one place is balanced by its equal and opposite action at another place. When it is taken into account in scientific calculations, the pressure of the system is referred to as absolute pressure. In this course, however, only gage pressures are discussed. (Absolute and gage pressures are defined in chapter 2.)

BOURDON TUBE GAGES

Bourdon tube gages are commonly used for measuring pressure in fluid power systems. The amount of pressure in a system is indicated on a gage scale calibrated for the system. By observing the pressure indicated on the gage scale, personnel operating the system can determine if the pressure is within the desirable operating range. Recorded gage readings are used as a means of insuring proper operating procedures, and also for determining the operating efficiency of the system.

The indicating element of a Bourdon tube pressure gage may be made in any one of a number of shapes. The most common shapes are the C tube, the spiral, and the helical. These three types of Bourdon tube gages are described in the following paragraphs.

C-Shaped Tube

A simple Bourdon tube pressure gage consists of a Bourdon tube, a gear-and-pinion mechanism, a dial, and a pointer. A Bourdon tube and a gear-and-pinion assembly are shown in figure 10-1. The curved hollow Bourdon tube (C-shaped) is closed at one end and connected to the fluid pressure at the other end. When pressure is applied the tube will try to straighten out, like a garden hose when the water is first turned on. Pressure acts equally on every square inch of area in the tube; but since the surface area on the outside of the curve is greater than the surface area on the shorter radius, the force acting on the outer surface will be greater than the force acting on the inner surface. When the pressure is applied the tube straightens out until the difference in force is balanced by the elastic resistance of the material composing the tube. As the movable end of the tube tries to straighten, it turns the gear on the pivot. This gear meshes with the gear fastened to the indicator needle shaft, and causes a reading on the pressure gage. The dial, which is not shown, is properly calibrated so that the needle points to the number which corresponds to the exact pressure. The

tube acts like a spring. When the pressure is removed, it returns to its normal position.

Simplex, vacuum, compound, duplex, hydraulic, differential, electric alarm, and depth are all types of Bourdon tube gages containing the C-shaped tube. A few of the more pertinent ones used in fluid power systems are discussed in the following paragraphs.

SIMPLEX.—A simplex Bourdon tube pressure gage is illustrated in figure 10-2. Gage cases are made of metal or plastic materials, which do not rust and are not affected by ammonia and other substances which injure some types of metal. One hand is connected to the pinion which protrudes up through the dial face. This pointer indicates pressure registered on the dial. The other hand, normally painted red, is always set to the normal working pressure of the system to which the gage is connected. This hand pivots on the dial and is manually positioned. On some gages, red lines are painted on the dial to indicate the minimum and maximum pressures which should be carried for the system to which the gage is connected. These lines should be properly labeled.

A simplex Bourdon tube gage may be used for measuring the pressure of steam, air, water, oil, and similar liquids or gases.

DUPLEX GAGE.—A duplex Bourdon tube gage has two separate tube mechanisms within the same case, each acting independently of the other. A pointer is connected to the gear mechansim of each tube, and each pointer moves over the face of the dial without interfering with the other pointer. (See fig. 10-3.)

Figure 10-2.—Simplex Bourdon tube pressure gage.

Figure 10-1.—Bourdon tube and gear-and-pinion mechanism.

One pointer on the face of the gage illustrated in figure 10-3 points to 0, indicating that no pressure is being exerted on the Bourdon tube to which it is attached. The other pointer of this gage, however, indicates that a pressure of 85 psi is being exerted on the tube to which it is attached.

Figure 10-4 shows a duplex Bourdon tube gage with the face removed. Note the position of the pointers, and also the separate connections to different pressure sources at the base of the case.

Duplex Bourdon tube gages are used for such purposes as showing the pressure drop between the inlet and outlet side of a strainer. The reading by each pointer indicates whether the strainer is clean or dirty; that is, if the pressure is much greater on the inlet side of the strainer, it indicates that foreign matter on the

strainer is very likely responsible for the higher pressure. A duplex gage serves many useful purposes in indicating the operating condition of certain parts or types of equipment.

HYDRAULIC BOURDON TUBE GAGE.—Hydraulic Bourdon tube gages are used to indicate high pressures, as on hydraulic rams (cylinders) used on the ship's steering gear and anchor windlasses. Because the pressure on these gages is so high, they are equipped with a slotted connecting link between the segment gear and the link adjustment to the tube to prevent the pointer from slamming back to 0 when the pressure on the gage is suddenly released. Without such a slotted link, the pointer or the gage mechanism could be damaged by a sudden release of pressure in the tube. Note the slotted link adjustment shown in the gear mechanism of the hydraulic gage illustrated in figure 10-5. Many systems which employ this type gage are equipped with gage snubbers (discussed later in this chapter) to prevent pressure surges from damaging the gage.

Many of the hydraulic gages used by the Navy have dials which indicate both the psi pressure and the corresponding tons of load on the ram. (See fig. 10-6.) The main pointer of this gage rests on 0, but the maximum pointer registers between 3800 and 3900. This means that during the operation the highest pressure reached was

Figure 10-5.—Slotted link in hydraulic Bourdon tube gage.

118042

188

Figure 10-6.—Hydraulic Bourdon tube gage.

slightly less than 3900 tons of load on the ram. At one point during the operation, the highest psi registered by the pointer was over 150, and while it was registering this pressure it carried the maximum pointer up with it. If the pointer had registered 200, for example, the maximum pointer would be pointing to 5100, the tons of load on the ram.

The spindle of the maximum pointer extends up through a small hole in the gage face and has a small knob which screws into the spindle. By turning this knob, the operator can set the maximum pointer. Always check, therefore, to see if the main pointer carries the maximum pointer along with it.

DIFFERENTIAL PRESSURE GAGE.—A differential pressure Bourdon tube gage is used to measure the difference in pressure between two pressures lines. (See fig. 10-7 (A).) It employs two Bourdon tubes in the same case. When the pressure exerted on the right tube is greater than that exerted on the left, the pointer moves to the right, and vice versa.

Tubes in a gage of this type are connected in a definite manner so as to be able to record differences in pressure from two sources. The small Bourdon tube (fig. 10-7 (B)) is connected to a stationary base. Through a system of levers, it is attached to the large Bourdon tube. The base of the large tube works on a pivot, so that the base can move either to the right or to the left at any time. The gage has one pointer, which is connected by linkage to the free end of the Bourdon tube.

The dial of the gage shown in figure 10-7 (A) has the 0 at the bottom-left. A differential pressure Bourdon tube gage with the 0 at this position should be used when the pressure from one source will always be greater than that at the other; but when the pressure from either source may be the greater, a gage with a 0 at the top of the dial should be used. If the 0 is at this position, the gage pointer has freedom for moving to the right or to the left.

CAUTION: When a gage with 0 at the bottom-left is used, turn on the valve to the high pressure source first, and then the valve to the low pressure source. Upon admittance to the line, pressure from the low pressure source will cause the pointer on the gage to retard toward zero.

Spiral and Helical Tubes

Two variations of the C-type Bourdon tube pressure gage are the spiral and the helical. The helical is sometimes referred to as helix. Both are made from tubing with a flattened cross section; both were designed to provide more travel of the tube tip, primarily for moving the recording pen of pressure recorders.

SPIRAL BOURDON TUBE.—The spiral form of Bourdon tube (fig. 10-8) is made by winding the ordinary Bourdon tube in the form of a spiral, having several turns, instead of the approximately 250-degree arc of the conventional Bourdon tube. This arrangement does not change the operating principle of the Bourdon tube, but simply has the effect of producing a tip movement equal to the sum of the individual movements that would result from each part of the spiral considered as a simple Bourdon tube. A given pressure, therefore, causes greater tip travel than the C-shaped Bourdon type.

HELICAL BOURDON TUBE.—The helical (or helix) form of element (fig. 10-9) has the Bourdon tube wound in the form of a helix, as illustrated. This arrangement increases the tip travel considerably. A center shaft is usually installed within the helix, and the pointer linkage is arranged so as to be driven from this shaft. The shaft, in turn, is rotated by the tip of the helix. This design transmits only the circular

CROWN GALL

Crown gall is one of the most prevalent and destructive diseases of shrubs and trees, particularly roses, pyracantha and stone fruits. The cause of the disease is a bacterium (Agrobacterium tumefaciens).

Symptoms - Infection of the host by the bacterium results in the development of overgrowths varying from the size of a pea to galls which weigh 50 lbs. or more. Galls occur commonly on roots but may also appear on crown, stems and even leaves of some plants. Gall development results in a gradual decline of the plant similar to that caused by nutrient deficiency.

Disease Cycle - Introduction of the crown gall bacterium into an area is most often by way of infected or contaminated nursery stock. The bacterium is

Fig. 1. Overgrowths on roots interfere with food and water supply causing gradual decline of the plant.

part of the tip movement to the pointer; this is the movement that is directly related to the change in pressure. Helical gages are generally confined to measurement of pressures in the range of 5 to 5,000 psi.

DIAPHRAGM GAGES

A diaphragm gage gives sensitive and reliable indications of small differences in pressure. It is often used to measure air pressure. This type of gage is usually designed by the manufacturer in accordance with specifications for a specific purpose and is calibrated accordingly. This does not mean, of course, that further adjustments may not be required when the gage is installed on a piece of equipment.

The indicating mechanism of a diaphragm gage consists of a tough, pliable, leather or neophrene rubber membrane connected to a metal spring which is attached by a simple linkage system to the gage pointer. Study the diaphragm gage illustrated in figure 10-10. Note the installation of the diaphragm in the gage frame and the positions of all parts of the gage. The size of the diaphragm affects its sensitivity

Figure 10-8.—Spiral Bourdon tube.

Figure 10-9.—Helical Bourdon tube.

13045

Figure 10-10.—Diaphragm air pressure gage.

in registering pressure—the larger the diaphragm the greater the sensitivity.

One side of the diaphragm is exposed to the pressure being measured; the other side is exposed to the atmosphere. When no pressure is exerted against the diaphragm, both it and the metal spring attached are in a neutral position. When pressure is applied to the diaphragm, it moves upward and pushes the metal spring ahead. As the spring is pushed up, it moves the pointer connected to it with the kinkless bead chain, to a higher reading on the dial. When pressure against the diaphragm decreases, it returns toward its neutral position and pulls the spring and pointer back with it. Thus, the reading on the scale of a diaphragm gage is directly proportional to the amount of pressure exerted on it by the force being measured.

SPRING-LOADED PRESSURE GAGE

The Bourdon tube gage is a delicate instrument and can be damaged very easily. In addition, as the range of fluid power applications widened to include systems where the pressure fluctuates rapidly, the gage sometimes causes trouble. The spring-loaded direct action gage was therefore developed, and since its introduction, has been increasingly accepted.

In the spring-loaded gage a piston is directly actuated by the fluid pressure to be measured and moves up a cylinder against the resistance of a spring, carrying a bar or indicator with it over a calibrated scale. In this manner all levers, gears, cams, and bearings are eliminated, and a sturdy instrument can be constructed.

Figure 10-11 shows the construction of the gage and the manner in which it operates. The parts up through the middle of the gage, from the needle at the bottom on through the packing piston and rod to the button at the top, form a unit which transmits fluid pressure to the sleeve against which the button rests. This sleeve surrounds the inner barrel of the gage. The sleeve is flanged at its base to provide a seat for a spring coiled around the barrel and for a cup to which the pressure indicator is attached. Fluid pressure compresses the spring, and the barrel rises out of the body, carrying the indicator up with it. The indicator moves against a pressure scale on the face of the gage. (See fig. 10-12.)

The spring-loaded gage is calibrated by comparing gage readings with known pressures. A small error can be corrected by loosening four screws on the face of the gage and sliding the scale up or down under the pointer. For larger errors, the adjustment screw which holds the spring in place can be tightened if the gage reading is to high, or loosened if the reading is too low. Turning the adjustment screw varies the compression of the spring. A sealing strip is provided to lock the adjustment screw in place after calibration.

While the spring-loaded pressure gage is satisfactory for ordinary fluid pressure measurements, it is not as accurate as the Bourdon tube gage. It is not a laboratory gage for exact readings, but a sturdily constructed working unit suitable for practical use. It is especially recommended for fluctuating loads.

The gage should be protected against vibration, excessive temperatures, corrosive fluids, and sudden high pressure. A petcock (plug valve) should be installed between the gage and the pressure system so that pressure can be applied slowly to the gage, and so that it will be protected against strain when not in actual use.

These gages should not be used in a system in which maximum pressure may exceed the maximum designated gage reading. Dropping a

13045
13046

Figure 10-11.—Spring-loaded gage.

gage may permanently damage the calibrated units. When gages are not in use they should be stowed in a dry place.

GAGE SNUBBERS

The irregularity of impulses applied to the fluid power system by some power pumps/compressors causes the pressure gage pointer to oscillate violently. This makes reading of the gage not only difficult but often impossible. Pressure oscillations and other sudden pressure changes existing in fluid power system will also affect the delicate internal mechanism of gages and cause either complete destruction of the gage or, often worse, partial damage, resulting in false readings. A pressure gage snubber is therefore installed in the line to the pressure gage.

The purpose of this unit is to dampen the oscillations and thus provide a steady reading and a protection for the gage. The pressure gage snubber shown in figure 10-13 consists of a two-port housing containing an orifice into which a floating plunger is inserted. The plunger tends to reduce the area of this orifice, thus

13047

Figure 10-12.—Spring-loaded gage scale.

increasing the dampening effect. The floating action of this plunger causes it to move back and forth in the orifice, thus making the small opening "self-cleaning." This reduction in surges results in a steadier pointer indication and a more accurate reading.

PRESSURE CONTROL DEVICES

Safe and efficient operation of fluid power systems, system components, and related equipment requires a means of controlling pressure. Different types of pressure control devices are utilized in fluid power systems to maintain the desired pressures in the systems and/or subsystems. For example, a system with a number of subsystems may require 3,000 psi to operate all subsystems except one, which requires only 1,500 psi. A pressure control valve is used to maintain the 3,000 psi in the main system and a pressure reducing valve is used to reduce the pressure to 1,500 psi before it enters the one subsystem.

Most pressure control valves are of the type which contains two systems of movable parts whose joint action is responsible for the operation of the valve. As stated in chapter 9, this type is classified as compound rather than simple. Some of the reasons compound valves are used for the control of pressure are explained in the next section of this chapter under relief valves.

Figure 10-13.—Pressure gage snubber.

The manner in which the most complicated pressure control valve operates will always conform to the hydraulic principles outlined in chapter 2. The valve will open or close because pressures are different over equal areas, because pressures are acting over unequal areas, or a combination of both reasons. In each

instance, inequality of opposed forces causes the valve to open or close. The forces may be set up by the opposition of fluid pressures, or by fluid pressure acting against a mechanical resistance, for example, the resistance set up by a spring.

Like all forces, the force exerted in a certain direction on the face of a valve is always exerted on an area standing exactly at a right angle to that direction. Thus in figure 10-14, if the fluid is under a pressure of 400 psi and the slanting surface (A) has an area of 10 square inches, the force acting in a slanting direction, at right angles to that surface, is 4,000 pounds. The force acting directly downward on surface (A), however, will depend on the horizontal area (B) which is directly beneath (A). If (B) has an area of 8 square inches, the downward force acting on surface (A) is 3,200 pounds (400 X 8).

RELIEF VALVES

A relief valve is simply a pressure limiting device. It is commonly used to prevent the pressure of a confined fluid from building up to a point at which the container would burst. The "pop-off" valve on a steam boiler, the weights on a pressure cooker, and the safety valve on a hot water tank are all relief valves. The pressure cap on an automobile radiator is a relief valve, used to prevent pressure from building up too high and bursting the radiator. Fluid power systems, even when operating normally, may temporarily develop dangerous excess pressures; for example, when an unusually strong work resistance is encountered. Relief valves are used to control this excess pressure. Their purpose is not to maintain flow or pressure at a given amount, but to keep pressure from rising above a definite level when the system is temporarily overloaded.

Figure 10-14.—Pressure acting on a slanted surface.

The main system relief valve must be large enough to allow the full output of the hydraulic pump to be delivered back to the reservoir. In the case of a pneumatic system, the relief valve controls excess pressure by discharging the excess fluid into the atmosphere.

Smaller relief valves, which are of the same design as the main system relief valves, are often used in isolated parts of fluid power systems. These smaller relief valves are used in parts of the system where a check valve or a directional control valve prevents pressure from being relieved through the main system relief valve.

These small relief valves are also used to relieve the pressure caused by thermal expansion (see glossary) of the fluids. Since the amount of fluid to be relieved is small, the valve can be small and still do its job.

All relief valves have an adjustment for increasing or decreasing the pressure at which they will relieve. The adjusting screw is usually covered by a cap, which must be removed before the adjustment can be made. Some relief valves are equipped with a handwheel and may be adjusted manually for different operations. To increase pressure at which the valve relieves, turn the adjusting screw or handwheel clockwise.

A simple two-port relief valve is shown in figure 10-15. The pressure from the system enters port (6) and pushes upward on the ball (5). If this pressure is high enough to overcome the force of spring (3), the ball will be pushed off its seat, and the fluid from the system can flow out port (4) to return, or to the atmosphere in pneumatic systems. The adjusting screw (1) increases or decreases the force of the spring, taking more or less pressure to unseat the ball.

Various modifications of the simple relief valve are used and efficiently serve the requirements of some fluid power systems. However, most systems require a compound relief valve. For a better understanding of the operation of relief valves, some of the undesirable characteristics of the simple relief valve are discussed in the following paragraphs.

1. Pressure adjusting screw.
2. Adjusting screwcap.
3. Compression spring.
4. Return port.
5. Ball.
6. Pressure port.

Figure 10-15.—Simple two-port relief valve.

It is because simple relief valves are unsatisfactory for some applications thatcompound relief valves were developed. A simple relief valve, such as the one illustrated in figure 10-15, with a suitable spring adjustment can be set so that it will open when the system pressure rises to say 500 psi. When it does open, however, the volume of flow to be handled may be greater than the capacity of the valve, so that pressure in the system may rise as much as several hundred pounds above the set figure before the valve spring brings the pressure under control. A simple relief valve would be effective under these conditions only if it were very large. In that case, however, it would work stiffly and would chatter back and forth.

In addition, when the system pressure is reduced, the valve will close at a pressure below the set figure. As indicated in figure 10-16, the seating surface of the valve must be wider than the pressure opening if the valve is to seat satisfactorily. The pressure in the system acts on the area of the valve open to it. In each case in figure 10-16, the force exerted directly upward by this pressure when the valve is closed depends on the horizontal area across the valve at (A). The moment the valve opens, however, the upward force exerted by the pressure will depend on the horizontal area of the valve at (B), which is necessarily greater than the area at (A). This leads to an upward jump in the action of the valve immediately after it opens, and it also sets up a greater force opposed to the closing of the valve than was needed to open it. As a result, the valve will close at a lower pressure than the pressure at which it opened. The same pressure acting over different areas produces forces proportional to the areas.

For example, assume a valve is set to open at 500 psi. (Refer to fig. 10-16.) When the valve is closed, the pressure acts on the area at (A). If this area is 0.5 square inch, an upward force of 250 pounds (500 X 0.5) will be exerted on the valve at the moment of opening. With the valve open, however, the pressure acts on the area at (B). If the area at (B) is 1 square inch, the upward force is 500 pounds, or double the force at which the valve actually opened. For the valve to close, pressure in the system would have to fall well below the figure at which the valve opened. The exact pressure at which the valve would close depends upon certain relations of the particular shapes of the valve element.

In some hydraulic systems the pressure in the return line must be overcome. This "back pressure" is caused by restriction in the return line. This pressure acting on top of the valve

Figure 10-16.—Pressure acting on different areas.

13050

Figure 10-17.—Operation of compound relief valve.

13052

cylinder. For example, counterbalance valves are used in some hydraulically operated fork lifts. The valve offers a resistance to the flow from the actuating cylinder when the fork is lowered. It also helps to support the fork in the UP position.

A counterbalance valve is illustrated in figure 10-18. The valve element is a balanced spool valve (4). The spool valve consists of two pistons permanently fixed on either end of a shaft. The inner piston areas of the pistons are equal; therefore, pressure acts equally on both areas regardless of the position of the valve, and has no effect on the movement of the valve—hence, the term balanced. A small pilot piston is attached to the bottom of the spool valve.

When the valve is in the closed position, the top piston of the spool valve blocks the discharge port (8). With the valve in this position, fluid, flowing from the actuating unit, enters the inlet port (5). The fluid cannot flow through the valve because the discharge port (8) is blocked. However, fluid will flow through the pilot passage (6) to the small pilot piston. As the pressure increases, it acts on the pilot piston until it overcomes the preset pressure of spring (3). This forces the spool up and allows the fluid to flow around the shaft of the spool valve and out the discharge port (8). Figure 10-18 shows the valve in this position.

During reverse flow, the fluid enters port (8). The spring (3) forces the spool valve (4) to the closed position. The fluid pressure overcomes the spring tension of check valve (7). The check valve opens and allows free flow around the shaft of the spool valve and out port (5).

The operating pressure of the valve can be adjusted by turning the adjustment screw (1), which increases or decreases the tension of the spring. This adjustment depends on the weight that the valve must support.

It is normal for small amounts of fluid to leak around the top piston of the spool valve and into the area around the spring (3). An accumulation would cause additional pressure on the top of the spool valve. This would require additional pressure to open the valve. The drain (2) provides a passage for this fluid to flow to port (8).

SEQUENCE VALVES

A sequence valve is used to control a sequence of operations; that is, enable one unit to automatically set another unit into motion. An example of the use of a sequence valve is in an aircraft landing gear actuating system.

6. Pilot passage.
7. Check valve.
8. Discharge outlet or reverse free flow inlet.

Figure 10-18.—Counterbalance valve.

In a landing gear actuating system the landing gear doors must be open before the landing gear starts to extend. Conversely, the landing gear must be retracted before the doors close. A sequence valve installed in each landing gear actuating line performs this function.

Figure 10-19 shows an installation of two sequence valves which control the sequence of operation of three actuating cylinders. Fluid from the directional control valve is free to flow into cylinder (A). The first sequence valve (1) blocks the passage of fluid until the piston in cylinder (A) moves to the end of its stroke. At this time, sequence valve (1) opens, allowing fluid to enter cylinder (B). This action continues in sequence until all three pistons move to the right.

13053

Figure 10-19.—Installation of sequence valves.

There are various types of sequence valves. Some are pressure controlled and some are mechanically controlled. One type of sequence valve operates similar to the counterbalance valve just described. In fact, valves are available which can be utilized as either a counterbalance valve or sequence valve. Two types of sequence valves are described in the following paragraphs. The first is pressure controlled and the second is mechanically controlled.

Pressure Controlled Sequence Valve

The operation of a typical pressure controlled sequence valve is illustrated in figure 10-20. The desired pressure is obtained by adjusting the tension of spring (2), which holds piston (1) in the closed position. Fluid from the directional control valve enters port (3), flows past piston (1) and enters the outlet port (4) to the first (primary) unit to be operated. When the pressure of the fluid flowing through the valve is below the adjusted setting, the force acting upward on piston (1) is less than the downward force of the spring (2). This holds the piston down and the valve is in the closed position as shown in figure 10-20 (A).

When the primary actuating unit completes its operation, the pressure increases in the valve. When the pressure increases sufficiently to overcome the force of spring (2), piston (1) rises. The valve is then in the open position, as shown in figure 10-20 (B). The fluid entering the valve takes the path of least resistance and flows through port (5) to the secondary unit. These valves usually contain a check valve to

allow free reverse flow from the secondary actuating unit to the primary unit. However, the sequencing action is provided only in one direction of flow.

Mechanically Operated Sequence Valves

Figure 10-21 illustrates a mechanically operated sequence valve. This valve is operated by the in and out movement of the plunger which extends from the body of the valve. The plunger is held in the extended position by a spring. The valve is mounted so that the plunger will be depressed by the primary unit.

Figure 10-21.—Mechanically operated sequence valve.

1305

a successful soil inhabitant and as such may persist in the soil for several years. Infection takes place through wounds only, as far as is known. When the organism is established in the soil, chewing insects play an important part in the infection process. If sanitary practices in grafting and pruning are not followed, infection may result and gall tissue may be mistaken for wound overgrowth due to imperfect grafting. A third means of entry of the bacterium is probably through natural wounds associated with development of lateral roots.

Control - The most satisfactory approach to crown gall control is through production of clean nursery stock. Choice of a growing area free of crown gall bacteria and chewing insects is important. Sanitary practices (dipping tools in a sterilizing solution) in grafting and storage are essential.

Plants purchased by the home gardener as bare root nursery stock often develop crown gall two or three years after planting. The incidence of infection in these cases can be reduced by dipping the root systems in an antibiotic solution (Agri-strep or Agri-mycin, 100 ppm) before planting. Follow label instructions. This treatment will kill bacteria on root surfaces and in incipient infections, preventing the development of the disease if the bacteria are not already in the soil.

in Plant Pathology

Note: The information given herein is supplied with the understanding that no discrimination is intended and no indorsement by the Arizona Extension Service is implied.

A check valve is incorporated between the fluid ports in the body. The check valve, either a ball or a poppet, is held against the seat by a spring. When seated, the check valve prevents a fluid flow through the valve. The check valve is unseated by the plunger as it is depressed into the valve by the primary unit.

Port (A) and the actuator of the primary unit are connected with a common line from the directional control valve. Port (B) is connected with a line to the actuator of the secondary unit. Fluid under pressure flows from the directional control valve to the primary unit and through port (A) to the seated check valve in the sequence valve. In order to operate the secondary unit, the fluid must pass through the sequence valve. The valve is located in such a position that the primary unit, as it completes its operation, will depress the plunger. The plunger unseats the check valve and allows the fluid to flow through the valve to the secondary unit.

This type sequence valve permits flow in the opposite direction. Fluid enters port (B), flows through the valve, and with a slight amount of pressure, unseats the check valve and flows through port (A).

PRESSURE REGULATORS

As the term implies, pressure regulators are used in fluid power systems to regulate the pressure. In pneumatic systems, the valve commonly referred to as a pressure regulator serves to reduce pressure. This type valve is described under pressure reducing valves in the next section. The pressure switch, described later, is often used in pneumatic systems to regulate systems pressure. The pressure regulator described in the following paragraphs is utilized in hydraulic systems.

Pressure regulators, often referred to as unloading valves, are used in hydraulic systems to unload the pump and to maintain and regulate system pressure between the maximum and the minimum. All hydraulic systems do not require pressure regulators. Many systems are equipped with variable displacement pumps, which contain a pressure regulating device, as described in chapter 7.

Pressure regulators are made in a variety of types by various manufacturers; however, the basic operating principles of all regulators are similar to the one shown in figure 10-22. The schematic diagram shows the regulator in both the cut-in and cutout positions.

A regulator is said to be in the cut-in position when it is directing fluid under pressure into the system. In the cutout position, fluid is bypassed into the return line and back to the reservoir. The difference between cut-in and cutout pressure is known as differential or operating range. For example, assume that a pressure regulator is set to cut in when the system pressure drops below 600 psi, and cut out when the pressure rises above 800 psi. The differential or operating range is 200 psi. Figure 10-22 (A) illustrates the regulator in the cut-in position and figure 10-22 (B) in the cutout position.

Notice that as the fluid is delivered from the pump, it goes to both the top and the bottom of the regulator. The construction of this regulator includes a piston 1 square inch in area, a piston rod, a steel ball one-fourth square inch in area, and a piston spring of 600 pounds force pushing the piston down. Until the pressure is great enough to push the piston up and unseat the ball, the fluid is directed to the system.

When the pressure on the piston builds up to 600 psi, the force applied on the piston face will be 600 pounds. (Force equals pressure times area—F = P x A.) In this case, the pressure is 600 and the area of the piston is 1 square inch; therefore, the force is 600 pounds. Since the spring pushes the piston down with a force of 600 pounds, the two forces on either side of the piston are balanced. However, the force holding the ball in place must be considered. This force, 600 x 1/4 square inch (area of the steel ball), equals 150 pounds. This force allows the fluid to continue to build up pressure in the system.

In figure 10-22 (B) the pressure has built up to 800 psi, or 800 pounds of force, pushing up on the piston. The spring pressure is constant (600 pounds); therefore, the resultant force is 200 pounds pushing the piston up. The force applied to the steel ball will also be 200 pounds (800 x 1/4). At this point the regulator is in the balanced state as both the upward and downward forces are equal. Any pressure in excess of 800 psi will move the piston up and push the ball off its seat. Since the fluid will always follow the path of least resistance, it will pass through the regulator and back to the reservoir. (See fig. 10-22 (B).)

The pump continues to operate, although it does not have to push the fluid out against the pressure. Therefore, it is not constantly under a load and the pump will operate under trouble-free conditions for a longer period.

13055

1. Bypass valve.
2. Pressure input.
3. Check valve.
4. System connection.
5. Piston.
6. Spring.
7. Line to reservoir.

Figure 10-22.—Hydraulic pressure regulator.

When the fluid from the pump is suddenly allowed a free path of return, the fluid in the system also tries to escape through the bypass. The check valve (3) will not allow this, however. The fluid in the system is trapped under pressure. The regulator is now in the cutout position. This fluid will remain pressurized until a unit is actuated, or until pressure is slowly lost through normal leakage within the system.

When the system pressure drops to a point where a further decrease in pressure might not provide sufficient force to operate one of the actuating units in the system, the spring (6) forces the piston (5) down, allowing the bypass (1) to close. When the bypass is closed, the fluid cannot flow directly to return. This causes the pressure to increase in the line between the pump and the regulator. This pressure will open check valve (3), and fluid will re-enter the system and build up the pressure to the desired maximum.

Therefore, when the system pressure lowers a certain amount, the pressure regulator will cut in, thus sending fluid into the system. When the pressure increases sufficiently the regulator will cut out allowing the fluid to flow through the bypass and back to the reservoir. As stated previously, the difference between the regulator cut-in pressure and cutout pressure is the differential or operating range. This prevents the regulator from cutting in or out with small changes in pressure. The pressure regulator serves to take the load off the pump and to regulate system pressure.

PRESSURE REDUCING VALVES

In some fluid power systems it is desirable, and often necessary, to operate a subsystem at a lower pressure than the main system. Pressure reducing valves are used for this purpose. For example, assume the operating pressure of a system is 1,500 psi. This pressure is required for all subsystems, except one which must be limited to 800 psi. A relief valve, adjusted to 1,500 psi, installed in the main system would allow system pressure to rise to the required 1,500 psi; however, the relief valve would not limit the subsystem pressure to 800 psi. A relief valve, adjusted to 800 psi, would protect the subsystem, but would also prevent the main system from developing the required 1,500 psi. Therefore, a system such as this requires a relief valve, adjusted to a setting just about 1,500 psi, installed in the main system and a pressure reducing valve, adjusted to 800

13056

psi, installed in the subsystem. In addition to reducing the pressure, a reducing valve regulates the pressure. That is, it maintains the reduced pressure at a constant level during operation of the subsystem.

Like all other valves, there are various designs and types of pressure reducing valves. Two types—the diaphragm-controlled and the pilot-controlled—are described in the following paragraphs.

Diaphragm-Controlled

A diaphragm-controlled pressure reducing valve is illustrated in figure 10-23. This type valve is commonly used in pneumatic systems. Because it serves to regulate reduced pressure to a subsystem, it is often referred to as a pressure regulator.

Control of fluid passing through this valve is effected by means of a pressure difference on

Figure 10-23.—Diaphragm-controlled pressure reducing valve.

13057

opposite sides of the diaphragm. The diaphragm is secured to the valve stem. Reduced fluid pressure from the valve outlet port flows through an internal passage to a diaphragm chamber below the diaphragm. An adjusting spring acts on the upper side of the diaphragm.

The amount of pressure applied by the fluid to the undersurface of the diaphragm varies according to the pressure in the outlet (reduced pressure) port. When the outlet pressure is greater than the spring pressure, the diaphragm is forced upward. Since this is an upward-seating valve, the upward movement of the stem tends to close the valve or at least to decrease the amount of flow through the valve. When the outlet pressure is less than spring pressure, the diaphragm and the valve stem are forced downward, opening the valve accordingly and increasing the amount of flow through the valve. This flow increases the pressure of the fluid in the outlet port. When the outlet pressure is equal to the spring pressure, the valve stem remains stationary and there is no flow of fluid through the valve.

The amount of pressure applied by the spring to the top of the diaphragm can be varied by turning the adjusting screw. Turning the adjusting screw clockwise increases the pressure applied by the spring to the top of the diaphragm, thus tending to open the valve. Turning the adjusting screw counterclockwise decreases the amount of spring pressure on the top of the diaphragm, thus tending to decrease the amount of pressure in the outlet port.

Pilot-Controlled

Figure 10-24 illustrates the operation of a pilot-controlled pressure reducing valve. This valve consists of an adjustable pilot valve, which controls the operating pressure of the valve, and a spool valve, which reacts to the action of the pilot valve.

12. Fluid chamber.
13. Fluid passage.
14. Fluid chamber.
15. Drain.

Figure 10-24.—Pilot-controlled pressure reducing valve.

13058

The pilot valve consists of a poppet (1), spring (2), and adjusting screw (3). The spool valve assembly consists of a spool valve (10) and spring (4).

Fluid under main system pressure enters the inlet port (11) and, under all conditions, is free to flow through the valve and out port (5). (Either port (5) or port (11) may be utilized as the high-pressure inlet port.)

Figure 10-24 (A) shows the valve in the open position. In this position, the pressure in the reduced-pressure outlet port (6) has not reached the preset operating pressure of the valve. The fluid flows through opening (7) and out through the reduced pressure port (6). The fluid also flows through passage (8), through the smaller passage (9) in the center of the spool valve, and into chamber (12). The fluid pressure at the outlet port (6) is therefore distributed to both ends of the spool. When these pressures are equal the spool is hydraulically balanced. Spring (4) is a low-tension spring and applies a slight downward force on the spool. Its purpose is to position the spool and to maintain opening (7) at its maximum size.

As the pressure increases in outlet port (7), this pressure is transmitted through passages (8) and (9) to chamber (12). This pressure also acts on the pilot valve poppet (1). When the pressure increases above the preset operating pressure of the valve, it overcomes the force of the pilot valve spring (2) and unseats the poppet (1). This allows the fluid to flow through the drain port (usually connected to the reservoir return line) and reduces the pressure in chamber (12).

Because the small size passage (9) restricts the flow to chamber (12), any additional pressure in the outlet port (6) will act on the bottom of the spool valve. This pressure overcomes the downward force of spring (4) and forces the spool up. As the spool moves upward, it restricts the flow through opening (7) and therefore causes the pressure to decrease in the reduced-pressure outlet port (6), (See fig. 10-24 (B).)

When the pressure decreases in outlet (6), the spool valve moves downward, allowing more flow through opening (7).

Reverse free flow from the reduced-pressure port (6) through the valve is possible only if pressure at port (6) is lower than the valve setting. If the pressure exceeds the valve setting, the valve will close, making reverse flow impossible. To insure reverse free flow, this type valve is often equipped with a check valve. The check valve is located between the high-pressure port (5) and the reduced-pressure port (6). Reverse flow will unseat the check valve and flow directly from port (6) to port (5).

PRESSURE SWITCHES

A pressure switch is actuated by a rise or drop in fluid pressure. The switch converts this pressure signal into an electric signal by closing the contacts in an electric circuit. The electric circuit is then used to perform some function in the fluid power system, such as opening and closing a valve, or stopping and starting a pump or compressor. Since fluid pressure is closely related to other system variables, pressure switches can detect fluid level, flow, and velocity. (In some instances, temperature changes can also be detected.)

The pressure signal, which can be either a rise or fall of fluid pressure, is converted into switch actuation by the pressure sensing element. This sensing element can be a piston, Bourdon tube, or diaphragm.

A pressure switch which utilizes a piston type element is illustrated in figure 10-25. The housing of this pressure switch has three external ports. Two of these ports (A and B) are connected to the main pressure line. Port (C) is connected to the return line. Within the housing are two pistons (D and E) and a hollow poppet valve (F). Piston (D) is held down by a spring, but is so placed that the end of its rod will move the ball upward and close the passage in the hollow poppet when pressure becomes great enough to overcome spring tension. Piston (E) is attached to an electrical switch by a piston rod. Pressure on this piston controls the switch. Upward movement of piston (E) turns the switch ON, and downward motion turns the switch OFF.

In figure 10-25, the switch is shown in the OFF position. System pressure, acting through port (B) and the internal passage, holds piston (D) up. When piston (D) is in this position, the opening in the hollow poppet is closed by the ball, and the poppet valve is held up off its seat. When the poppet valve is off its seat, the upper chamber is connected to system pressure, and the pressure acting on the top of piston (E) is the same as the pressure acting on the bottom. Since the area of the top of piston (E) is greater than the area of the bottom (because of the area of the piston rod), the force holding it down is greater than the force holding it up. The switch will therefore remain in the OFF position until

 K00013059

system pressure is reduced. As the system pressure drops, the large spring forces piston (D) down and allows the poppet valve to seat. Any further decrease in pressure will allow the ball to move away from the opening in the hollow poppet. This action will connect the upper chamber to the return lines through the hollow poppet and the pressure in the upper chamber will drop to zero. The instant this occurs, the force holding piston (E) down will drop to zero and system pressure acting on the bottom of piston (E) will move it up and snap the switch ON.

The piston type sensing element is best suited for high pressure. The major disadvantages of the piston sensing element is that the piston is relatively insensitive to small pressure changes.

The Bourdon tube sensing element is similar in operation to the Bourdon tube pressure gage, previously described. Instead of moving a pointer, as in the pressure gage, the movable end of the tube turns the switch ON and OFF. The Bourdon tube sensing element is capable of operating over a wide range of pressures. It is an accurate pressure switch and is capable of operating at pressures as high as 12,000 psi. Its major disadvantages are cost and its inability to withstand surge pressures.

The diaphragm sensing element is ideally suited for low pressures (up to 400 psi). The diaphragm sensing element is similar in design and operation to the diaphragm pressure gage described earlier in this chapter. It is highly accurate where the diameter of the element is from 2 to 4 inches. The diaphragm sensing

Figure 10-25.—Pressure switch.

09060

element offers fast response to fluid pressure changes.

HYDRAULIC FUSES

A hydraulic fuse is a protective device designed to assure that all of the fluid in a system does not leak out in case some section of the system develops a leak. When hydraulic fuses are used in a hydraulic system, they are installed at various appropriate locations in the system so that the system is divided into sections. When a leak occurs in a section, the hydraulic fuse limits the fluid loss to the amount contained in the small section of the system that is isolated. Fuses are commonly used in aircraft hydraulic systems. If a leak develops in a subsystem while the aircraft is flying, or a hydraulic line is shot away during combat, a fuse prevents excessive loss of fluid, thus permitting operation of the remaining subsystems.

As its name implies, the hydraulic fuse is very similar to the electric fuse. When too much current flows, the electric fuse blows and opens the circuit. The hydraulic fuse stops the flow when too much fluid has passed through it. It actually measures the quantity of fluid that is flowing, and is sometimes referred to as a quantity measuring fuse.

Figure 10-26 shows a schematic of a hydraulic fuse in the static position. This is the position the valve assumes whenever the subsystem it protects is not in operation, under normal conditions, and there is no flow in either direction. The valve (fig. 10-26) can function as a fuse only when the fluid flows from left to right. It cannot measure the quantity of fluid if the flow is in the opposite direction. For this reason, the hydraulic fuse must be connected to the pressure line leading to the directional control valve of the subsystem, or a fuse must be located in each alternating line. Figure 10-27 shows these two methods of installation.

Figure 10-28 (A) depicts a hydraulic fuse in the flow position. The fluid enters the entrance port (1) where it divides, flowing along the side passages and on to the center of the valve through the drilled holes. Here, it forces the sleeve (5) back, allowing the fluid to flow out the other drilled holes, around the outside passages, and out the exit port (6). As the fluid flows through the valve, some of the fluid entering the entrance port (1) flows through the orifice (2). This fluid slowly forces the piston (3) to the right because, due to fluid flow, there is less pressure on the right side of the piston than on the left. If more fluid flows than is normally required, the piston will finally move to the right until it reaches sleeve (5). The piston blocks the holes drilled through from the outer passages and thus stops fluid flow. In this position, the valve is fused, as is shown in figure 10-28 (B). There is a continual flow of fluid through the fuse until the piston moves far enough to block the holes. Thus, the quantity of fluid allowed to flow before the valve fuses is dependent upon the time it takes the piston to move to the right. A large orifice causes the piston to move faster, allowing less fluid to flow through the outer passages of the valve before it fuses. A small orifice causes the piston to move slower, thereby allowing a greater volume of fluid to flow before the valve fuses.

The size of the orifice used is dependent upon the quantity of fluid needed to move the actuating unit to its extreme travel. For example, an actuating cylinder that requires 40 cubic inches of fluid to extend fully, requires a fuse of slightly larger capacity than the actuating cylinder to insure, under normal operating contions, that the valve will not fuse before the cylinder has reached its full limit of travel. Since the orifice cannot be removed from a fuse, fuses are available with different sized

Figure 10-26.—Hydraulic fuse in the static position.

13061 13061

Figure 10-27.—Hydraulic fuse installations.

orifices. Each fuse has the flow capacity clearly marked on its body.

The check valve (4) is incorporated in the fuse to allow for reverse flow, should the fuse be connected in an alternating line. Figure 10-28 (C) shows the reverse flow position with the check valve open. The sleeve (5) and piston (3) are forced to the left, the flow of fluid opens the check valve (4) and allows free reverse flow.

During normal operation the valve nearly fuses each time the full actuator capacity flows through it. When the actuator completes the full travel, the flow of fluid stops, pressure equalizes in all parts of the fuse, and the large spring forces the sleeve and piston to the static position. The fuse also resets to the static position when the fluid pressure is relieved in the line containing the fuse.

If an alternating line should burst, or a seal in an actuating unit ruptures, the fuse allows some its normal flow capacity to escape. At that time it fuses, preventing further fluid loss from the system. Although the hydraulic fuse allows of the fluid to escape from the system, enough fluid remains for normal operation of the other subsystems.

CHAPTER 11

DIRECTIONAL CONTROL VALVES

Directional control valves are designed for the specific purpose of directing the flow of fluids in fluid power systems. (These valves are also referred to as selector valves, transfer valves, or control valves.) It may be desired, for example, to perform a work operation by driving a piston or ram back and forth in its cylinder. A directional control valve, which functions alternately to admit fluid to and from each end of the cylinder, is used to make this operation possible.

Directional control valves for hydraulic and pneumatic systems are similar in design and operation. One major difference—the return port of a hydraulic valve is ported through a return line to the reservoir; while the similar port of a pneumatic valve is ported to the atmosphere and is commonly referred to as an exhaust port.

Directional control valves may operate by differences of pressure acting on opposite sides of the movable parts, or they may be positioned manually, mechanically, or electrically. Often two or more methods of operating the same valve will be utilized in different phases of its action.

CLASSIFICATION

Directional control valves may be classified in numerous ways. One way is by the type of valving element. Some of the most common types of valve elements are described in the following paragraphs.

POPPET

Figure 11-1 illustrates the operation of a simple poppet valve. The valve consists primarily of a movable poppet which closes against a valve seat. In the closed position, fluid pressure from the inlet tends to hold the valve tightly closed. A small amount of movement from a force applied to the poppet stem opens the poppet and allows fluid to flow through the valve.

The steel poppet fits into the center bore of the seat. There is a lapped or closely machined surface between the poppet and seat, so that the center bore will be sealed when the poppet is seated. This action is similar to the valves of an automobile. An O-ring seal is usually installed on the stem of the poppet to prevent leakage past this portion of the poppet. In some valves the poppets are held in the seated position by springs. The number of poppets in a particular valve depends on the design and purpose of the valve.

There are various methods used for shifting the poppets from one position to another. Some of the most common methods are described later.

ROTARY SPOOL

The rotary type directional control valve has a round core with one or more passages or recesses in it. The core is mounted within a sleeve. (See fig. 11-2.) As the core is rotated (generally by a hand lever or a knob) within the stationary sleeve, the passages or recesses connect or block the ports in the sleeve.

SLIDING SPOOL

Figure 11-3 shows a sliding spool valve. The valve element is so named because of its shape, and it slides back and forth to block and uncover ports in the housing. Some manufacturers refer to this element as a piston type. The inner piston (lands) areas are equal. Thus, pressure within the valve from the inlet ports acts equally on both inner piston areas regardless of the position of the spool. Sealing is usually accomplished by a machined fit between the spool and the valve body or sleeve. For valves with more ports, the spool is designed with more pistons or lands on a common shaft.

FIREBLIGHT

by

Alice M. Boyle & A. D. Davison[1]

Fireblight is a common and often destructive disease of some members of the rose family (Rosaceae). Pears, apple, and quince are the most susceptible hosts. In Arizona, the disease is often very destructive in the stone fruits and causes severe damage in such ornamentals as hawthorn, pyracantha, cotoneaster, and loquat. Fireblight is caused by a bacterium, *Erwinia amylovora*.

Symptoms - Bacteria that have overwintered in "hold-over" cankers constitute the chief source of inoculum for spring infection. Bacterial ooze from these cankers is carried by ants and flies to the blossoms, causing initial infection. Bacteria may then by spread from blossom to blossom by honeybees. Rain may also be a major factor in spread of the pathogen from hold-over cankers to blossoms.

Control - Blossom sprays are suggested to protect the susceptible blooms from infection. Bordeaux 1/2-1/2-100 or Agrimycin 100, 50 to 100 parts per million are satisfactory. Agrimycin 100 is suggested when maximum temperature is above 65° F. For severe disease situations use 100 ppm, for light blight problems use 50 ppm. Bordeaux 1/2-1/2-100 should be applied during quick drying conditions to avoid possible fruit russet. Fog the trees rather than drenching them.

Fig. 1. Thin layers of bark often peel from small infected limbs and twigs.

(1) Plant Pathologist and Extension Specialist in Plant Pathology, respectively.

1304

Figure 11-1.—Operation of a simple poppet valve.

Like all classes of directional control valves, various methods are utilized for positioning the sliding spool valve. Some of the most common methods are described under the different types of valves later in this chapter.

Balls, cones, and sleeves are also types of valving elements used in directional control valves. Their use is usually limited to check valves, which are described in the next section.

CHECK VALVES

Check valves are the most commonly used valves in fluid power systems. Although not always classified as such, check valves permit flow in one direction and prevent flow in the other, and can be considered as one-way directional control valves.

Figure 11-2.—Parts of a rotary directional control valve.

Check valves may be installed independently in a line to allow flow in one direction only. This is indicated in the simple system described in chapter 4. Check valves are also incorporated as an integral part of some other valve, such as the sequence valve, counterbalance valve, and pressure reducing valve described in chapter 10. A modification of the check valve—the orifice check valve (described in chapter 9)—allows full flow in one direction and a limited or restricted flow in the opposite direction.

Figure 11-3.—Operation of a sliding spool directional control valve.

13065

Check valves are available in various designs. The valving element may be a sleeve or cone, ball, poppet, piston, spool, or disc. The force of the fluid in motion opens a check valve, while it is closed by back flow, by the action of a spring, or by gravity.

Figure 11-4 shows a swing type check valve (flapper valve). In the open position the flow of fluid forces the hinged disc up and allows free flow. Flow in the opposite direction, with the aid of gravity, forces the hinged disc to close the passage and blocks the flow. This type valve is sometimes designed with a spring to assist closing of the valve.

Figure 11-5 shows a vertical check valve in which the closing of the valve is influenced considerably by the force of gravity.

Figure 11-6 shows examples of spring-loaded check valves. Figure 11-6 (A) shows the cone or sleeve type. As fluid pressure is applied in the direction of the arrow, the sleeve (2) is forced off the check valve seat (3). This allows fluid to pass freely through the drilled openings of the sleeve. Figure 11-6 (B) shows a ball type check valve. As the pressure is applied, the ball moves off its seat, thus allowing fluid to flow freely through the valve.

The spring is installed in the valve to hold the cone or ball on its seat whenever the fluid is not flowing. The spring (1) is very weak; the pressure differential with full flow is usually about 8 psi. When fluid attempts to flow in the opposite direction, the pressure developed helps to hold the ball or cone on its seat and creates a tighter seal. Since this type valve is not influenced by

Figure 11-4.—Swing type check valve.

Figure 11-6.—Spring-loaded check valves.

gravity, it is used in many applications in the fluid power systems of aircraft and missiles.

STARTING VALVES

Starting valves are commonly used in pneumatic systems of missiles. These valves provide a positive block in the discharge (output) side of the air supply (flask). Many of these are designed to be opened by retracting a pin, either manually or electrically. Retraction of the pin permits gas to pass from the flask, thus starting operation of the pneumatic system. Figure 11-7 shows the operation of a starting valve. When the pin is released, inlet pressure acting on the valve shoulder causes piston movement to the left. The function of the spring is merely to absorb the shock of the rapid piston movement.

SHUTTLE VALVES

In certain types of fluid power systems, the supply of fluid to a subsystem must be from more than one point of origin in order to meet system requirements. In some systems an emergency system is provided as a source of pressure in the event of normal system failure. For example, in aircraft hydraulic systems the emergency source of pressure may be compressed air. The emergency system will usually actuate only those units essential in getting the aircraft safely on the ground and stopping it. When using the emergency system, the pressure must be directed to the unit concerned; and yet, emergency pressure must not enter the normal system. To allow operating pressure to reach the actuating unit and still not enter the other system, a shuttle valve is installed in the working line to the actuating unit. The shuttle valve is small and simple, but is a very important component.

The main purpose then of a shuttle valve is to isolate the normal system from an alternate or emergency system.

A typical shuttle valve is shown in figure 11-8. The body contains three ports—normal system inlet port, alternate or emergency system inlet port, and the outlet port. A shuttle valve used to operate more than one actuating unit may contain additional unit outlet ports.

Enclosed in the body is a sliding part called the shuttle. It is used to seal one of the two inlet ports. A shuttle seat is installed at each inlet port; and during operation, the shuttle is held against one of these seats, sealing off that port. These parts are held in the body by end caps. External leakage is prevented by an O-ring gasket at each end cap.

The shuttle may be one of four types—a sliding plunger, a spring-loaded piston, a spring-loaded ball, or a spring-loaded poppet. In shuttle valves employing a shuttle spring, the shuttle is normally held against the alternate system inlet port by the spring.

When a shuttle valve is in the normal operation position, fluid has a free flow from the normal system inlet port to the unit outlet port. The shuttle is seated against the alternate system inlet port, and held there by normal system pressure and by the shuttle spring. The shuttle remains in this position until the alternate system is operated. This action directs fluid under pressure from the alternate system to the shuttle valve and forces the shuttle from the alternate system inlet port to the normal inlet port. Fluid from the alternate system then has a free flow to the unit outlet port, but is prevented from entering the normal system by the shuttle.

TWO-WAY VALVES

A two-way, sliding spool directional control valve is shown in the open and closed positions in figure 11-9. As the spool is moved back and

13067

Figure 11-7.—Starting valve.

forth, it either allows fluid to flow through the valve or prevents flow. The spool cannot move back and forth by differences in pressure set up within the cylinder, since the forces there are balanced. As indicated by the arrows against the piston heads, the same pressure acts on equal areas on their inside surfaces; and when the input passage is blocked, the piston blocking it is acted on all around its circumference by the same pressure.

A number of features common to most spool type valves can be noted in figure 11-9. The drain openings at either end of the spool are needed so that back pressure will not be built up and hinder movement of the spool. When spool valves become warn, they may lose balance because of greater leakage on one side of the spool than on the other. In that event the spool would tend to stick in moving back and forth. Small grooves are therefore machined around the sliding surfaces of the spool; and, in the case of hydraulic valves, leaking liquid will encircle the spools and keep them lubricated and centered.

THREE-WAY VALVES

The three-way directional control valve is designed to operate an actuating unit in one direction; it permits either the load on the actuating unit or a spring to return the unit to its original position. Two different designs of poppet type, three-way directional control valves are discussed in the following paragraphs.

CAM-OPERATED

Figure 11-10 illustrates the operation of a cam-operated, three-way, poppet type directional control valve. Figure 11-10 (A) shows fluid pressure forcing the piston outward against

Figure 11-8.—Shuttle valve.

13068

Figure 11-9.—Two-way, sliding spool directional control valve.

a load. The upper poppet (2) is unseated by the inside cam (5), permitting fluid to flow from line (3) into the cylinder to actuate the piston. The lower poppet (1) is seated, sealing off the flow to the return line (4).

In figure 11-10 (B) the control valve has been turned to the opposite setting, and the upper poppet (2) is seated, sealing the fluid from the pressure line (3). The lower poppet (1) is unseated by the outside cam (6) so that the fluid forced from the cylinder can flow through the control valve and out the return port (4). In pneumatic valves, the return port (4) is open to the atmosphere.

PILOT-OPERATED

A pilot-operated, poppet type, three-way directional control valve is illustrated in figure 11-11. Valves of this design are often used in pneumatic systems. This is a normally closed valve and is forced to the open position by fluid pressure entering the pilot chamber. The valve contains two poppets connected to each other by a stem. The poppets are integral with diaphragms which hold them in a centered position. When the pilot chamber is not pressurized, the lower poppet is seated against the lower valve seat. Fluid can flow from the supply line through the inlet port and through the holes in the lower diaphragm to fill the bottom chamber. This pressure holds the lower poppet tightly against its seat and blocks flow from the inlet port through the valve. At the same time, due to the common stem, the upper poppet is forced off its seat. Fluid from the actuating unit flows through the open passage, around the stem, and through the exhaust port to the atmosphere.

When the pilot chamber is pressurized, the force acting against the diaphragm forces the poppets down. The upper poppet closes against its seat. The lower poppet opens, and the passage from the supply inlet port to the cylinder port is open so that fluid can flow to the actuating unit.

The normally open valve is similar in design to the normally closed valve. (See fig. 11-12.) When no pressure is applied to the pilot chamber, the upper poppet is forced off its seat and the lower poppet is closed. Fluid is free to flow from the inlet port through the cylinder port to the actuating unit. When pilot pressure is applied, the poppets are forced downward, closing the upper poppet and opening the lower poppet. Fluid can now flow from the cylinder through the valve and out the exhaust port to the atmosphere.

FOUR-WAY VALVES

Four-way directional control valves are commonly used to control cylinders, motors, or other valves. The typical four-way directional control valve has four ports—a pressure port, a return or exhaust port, and two working ports. The pressure port is connected to the main pressure line, the return port is connected to the reservoir. In the valves used in pneumatic systems, this port is usually vented to the atmosphere. The two working ports are connected by lines to the actuating unit. Some of the different types of four-way directional control valves are described in the following paragraphs.

POPPET TYPE

Figure 11-13 illustrates a typical four-way poppet type directional control valve. This is a manually operated valve and consists of a group of conventional spring-loaded poppets. The poppets are enclosed in a common housing and

13069

1. Lower (return or exhaust) poppet.
2. Upper (pressure) poppet.
3. Pressure line.
4. Return or exhaust port.
5. Inside cam.
6. Outside cam.

Figure 11-10.—Three-way, poppet type directional control valve (cam-operated).

are interconnected by ducts so as to direct the flow of fluid in the desired direction.

The poppets are actuated by cams on a camshaft, as shown in figure 11-14. They are arranged so that rotation of the shaft by its controlling lever will open the proper combinations of poppets to direct the flow of fluid through the desired line to the actuating unit. At the same time, fluid will be directed from the opposite line of the actuating unit through the valve and back to the reservoir or exhausted to the atmosphere.

13070

Figure 11-11.—Three-way, poppet type, normally closed directional control valve (pilot-operated)

Figure 11-12.—Three-way, poppet type, normally open directional control valve (pilot-operated).

This type valve is provided with a stop for the camshaft. This is an integral part of the shaft and strikes against a stop pin in the body to prevent overrunning.

The poppets are held to their seats by springs, and a camshaft is used to unseat them and allow a flow of fluid through the valve. The camshaft is controlled by the movement of the handle. The valve may be operated by manually moving the handle, or the handle may be connected by mechanical linkage to a control handle located at a convenient place some distance from the valve. The camshaft has a raised flange on the control handle end to prevent it from moving through the housing. A nut screws on the opposite end to secure it to the housing. There are three O-ring packings on the camshaft to prevent internal and external leakage. The camshaft has two lobes, or raised portions. The contour, or shape, of these lobes is such that when the shaft is placed in the neutral position the camming lobes will not be contacting any of the poppets.

When the camshaft is rotated, either clockwise or counterclockwise from neutral, the cam lobes unseat the desired poppets and allow a flow of fluid through the valve. One cam lobe

13071

Figure 11-13.—Poppet type, four-way, directional control valve.

operates the two pressure poppets, and the other lobe operates the two return/exhaust poppets. To stop rotation of the camshaft at the exact position, a stop pin is secured to the body and extends through a cutout section of the camshaft flange. This stop pin prevents overtravel by insuring that the cam lobes stop rotating when the poppets have unseated as high as they can go, where any further rotation would allow them to return to their seats.

This directional control valve has three positions—neutral and two working positions. In the neutral position, the camshaft lobes are not contacting any of the poppets. This assures that the poppet springs will hold all four poppets firmly seated. With all poppets seated, there is no fluid flow through the valve. This also blocks the two working ports; so when this valve is in neutral, the fluid in the actuating unit is trapped. To allow for thermal expansion buildup, thermal relief valves must be installed in both working lines.

By moving the control handle either direction from neutral, the camshaft is rotated. This rotates the lobes, which unseat one pressure poppet and one return/exhaust poppet. The valve is now in a working position. Pressure fluid, entering the pressure port, travels through the vertical fluid passages in both pressure poppet seats. Since only one pressure poppet is unseated by the cam lobe, the fluid flows past the open poppet to the inside of the poppet seat. From there it flows out the diagonal fluid passages, then out one working port and to the actuating unit.

Return fluid from the actuating unit enters the other working port. It then flows through the diagonal fluid passages, past the unseated return poppet, through the vertical fluid passages, and out the return/exhaust port. By rotating the camshaft in the opposite direction until the stop pin hits, the opposite pressure and return poppets are unseated, and the fluid flow is reversed. This causes the actuating unit to move in the opposite direction. This action can be observed by studying figure 11-15.

ROTARY SPOOL TYPE

Four-way valves of this type are most frequently used as pilot valves to direct flow to other valves. Fluid is passed from one source of supply through the rotary valve on to another directional control valve, where it positions the valve to direct flow from another source to one side of an actuating unit. Through a return line, fluid is carried from the other end of the main valve through the rotary valve to return/exhaust.

Figure 11-16 shows the operation of a rotary spool valve. Figures 11-16 (A) and 11-16 (C) show the valve set to deliver fluid to another valve, while figure 11-16 (B) shows the valve in neutral position, with all passages through the valve blocked.

Rotary spool valves can be operated manually, mechanically, electrically, or by fluid pressure.

SLIDING SPOOL TYPE

The sliding spool four-way directional control valve is similar in operation to the two-way valve previously described. It is simple in principle of operation and is probably the most durable and trouble free of all four-way directional control valves in current use. Some manufacturers refer to this type valve as a piston type.

1T0613072

Figure 11-14.—Cutaway view of directional control valve.

Although the first valve described here is a manually operated type, the same principle is used in many remotely controlled directional control valves. An understanding of the operation of this valve will therefore aid in understanding the more complicated solenoid-operated valve discussed later.

Figure 11-17 is a cutaway view of a typical four-way sliding spool directional control valve. The valve body contains four fluid ports—pressure, return/exhaust, and two working ports. (The working ports are referred to as cylinder ports in this discussion; however, this type valve may be used to control other types of actuating units.) A large bore has been drilled lengthwise through the body, and all four fluid ports connect into this main bore at intervals along its length. There is also a drilled passageway in the body that runs along the main bore. This passageway is used to connect one of the cylinder ports to the return/exhaust port.

A hollow steel sleeve (3) fits into the main bore of the body. Around the outside diameter of the sleeve are six O-ring gaskets. As the sleeve is inserted into the main bore, these O-rings form a seal between the sleeve and the body. This creates five chambers around the sleeve, each chamber being formed by two of the O-ring gaskets. Each one of these chambers is lined up with one of the fluid ports in the body. The drilled passageway in the body accounts for the fifth chamber which results in having the two outboard chambers connected to the return/exhaust port. The sleeve has a pattern of holes drilled through it to allow fluid to flow from one port to another. Between each O-ring gasket a series of holes are drilled into the hollow center of the sleeve.

13073

Figure 11-15.—Working view of poppet type, four-way directional control valve.

Figure 11-16.—Operation of rotary spool, four-way, directional control valve.

To prevent the sleeve from moving, a sleeve retainer bolt or pin secures it to the body. When this bolt is inserted into the body, it protrudes slightly into the main body bore. A slot around the sleeve lines up with this bolt. In this manner, the sleeve is keyed to the body.

The sliding spool (5) fits into the hollow center of the sleeve. This spool is similar to the spool in the two-way valve, except this spool has three pistons or lands. These lands are lapped or machine fit to the inside of the sleeve.

One end of the sliding spool is connected to a control handle either directly or by mechanical linkage to a more desirable location. When the control handle is moved, it will then position the spool within the sleeve. The lands of the spool then line up different combinations of fluid ports, thereby directing a flow of fluid through the valve.

The detent spring (6) is a clothespin type spring, secured to the end of the body by a spring retaining bolt (7). The two legs of the spring extend down through slots in the sleeve and fit into the detents. The spool is gripped between the two legs of the spring. To move the spool, enough force must be applied to spread the two spring legs and allow them to snap back into the next detent, which would be another position.

Figure 11-18 illustrates the operation of the manually operated sliding spool directional control valve. In the upper view (A), the valve is in the neutral position, with the detent spring clamped in the center detent of the sliding spool. The center land is lined up with the pressure port, preventing fluid from flowing into the valve through this port. The return/exhaust port is also blocked, so there is no flow through that port. With both pressure and return ports blocked, fluid in the actuating lines is trapped. For this reason, a thermal relief valve is usually installed in each actuating line when this type valve is used.

Figure 11-18 (B) shows the valve in one working position with the sliding spool retracted. The detent spring is in the outboard detent, locking the sliding spool in this position. The lands have shifted inside the sleeve, and the ports are opened. Pressure fluid now enters

13074

Usually three applications are needed for effective fireblight control (full bloom petal fall and late secondary bloom). Copper-lime dust (10-90) and fixed copper may be used following manufacturer's directions.

Canker Removal and Summer Pruning - Winter is the best time to remove blighted twigs and branches. Cut back 4 or more inches from the canker; remove all dead and discolored bark down to the wood. The ends of the cut should be brought to a point to encourage rapid healing. Paint the area with a disinfectant*. When removing blighted twigs and branches in the summer remember that the bacteria are in a very active stage.

Fig. 2. Large hold-over cankers are sources of bacteria for new infections in the spring.

Therefore, prune at least 12 to 14 inches below the last signs of infection. Disinfect* tools after each cut to avoid mechanical spread by tools. Since damage by fireblight is more severe in succulent tissues, regulation of soil fertility to minimize such growth is an important part of control.

*Disinfectant - For home and garden, use a 10% solution of household bleach; in commercial orchards prepare the disinfectant by dissolving 8 half-gram tablets of cyanide of mercury and 8 half-gram tablets of bichloride of mercury in 1 pint of warm water. To this add 3 pints of commercial glycerine. Be careful when using the material as it is very poisonous and can be absorbed through the skin.

Figure 11-17.—Cutaway view of sliding spool four-way directional control valve.

the sleeve, passes through it by way of the drilled holes, and leaves through cylinder port (C2). Return fluid, coming from the actuator, enters port (C1), flows through the sleeve, and is directed out the return port back to the reservoir or exhausted to the atmosphere. Fluid cannot flow past the spool lands because of the lapped surfaces.

Figure 11-18 (C) shows the valve in the opposite working position with the sliding spool extended. The detent spring is in the inboard detent. The center land of the sliding spool is now on the other side of the pressure port, and now the pressure fluid is directed through the sleeve and out port (C1). Return flow coming in the other cylinder port is directed to the drilled passageway in the body. It flows along this to the other end of the sleeve where it is directed out of the return/exhaust port.

There are many variations of the sliding spool directional control valve. For example, many valves of this type have two return/exhaust ports. In the case of hydraulic systems, the two ports are connected to a common return line to the reservoir. There are also many different methods of controlling the sliding spool valve.

Figure 11-19 shows a schematic view of a rotary directional control valve used as a pilot valve to control flow to the sliding spool valve. Fluid pressure can be directed to either end of the sliding spool valve which positions the spool and directs flow to and from the actuating unit.

The sliding spool valve, like other types of directional control valves, may be operated electrically. This is usually accomplished through the use of one or more solenoids.

A solenoid may be defined as a hollow or tubular shaped electric coil, made up of many turns of fine insulated wire, and possessing the same properties as an electromagnet. The hollow coil imparts linear motion to a movable iron core (or plunger) placed within the hollow coil of the solenoid.

Figure 11-20 shows a solenoid-operated directional control valve. This valve is sometimes referred to as a transfer valve. The

13075

Figure 11-18.—Operation of sliding spool four-way directional control valve.

13076

Figure 11-19.—Sliding spool valve controlled by rotary valve.

valve is illustrated in the neutral position with no flow through the valve. The valve is operated by energizing either of the solenoids. This may be accomplished by a manually operated electric switch or, for example in missile systems, automatically by the response of the solenoids to electric signals generated by the missile computer network.

The object is to move the actuator, which is mechanically linked to the device to be operated.

If solenoid (1) in the figure is energized, it will cause the valve spool to move to the left. This will permit pressurized fluid to be ported to the right-hand side of the actuator and cause it to move to the left. If solenoid (2) is energized, the valve spool will move to the right, causing actuator movement to the right in the same manner. In either position, fluid can flow from the opposite side of the actuator through the valve and out the corresponding return/exhaust port.

Solenoids are often used to control a small pilot valve which directs flow to either end of a sliding spool valve. The fluid pressure acting

Figure 11-20.—Solenoid-operated sliding spool directional control valve.

13077

Figure 11-21.—Servo valve.

on the end of the sliding spool valve will position the spool for the desired operation.

SERVO VALVES

The four-way valves just described have one disadvantage in that they operate in an on-off manner. This means that they provide positive movement of the actuating unit; that is, full movement in either direction. A finer control is desirable in many fluid power systems. The servo valve provides this control.

Servocontrol may be defined as a control actuated by a feedback system which compares the output with the reference signal and makes

13078

corrections to reduce the differences. The feedback signal may be provided by fluid pressure, mechanical linkage, electrical signals, or a combination of the three.

One type of hydraulic servo valve is illustrated in figure 11-21. The valve is controlled by the two solenoids, which receive the electric feedback signals through a followup system from the actuated unit. With neither of the windings energized (or a balanced current flowing through both), the magnetic reed is centered as shown in figure 11-21. In this condition, high-pressure fluid from the input line cannot pass to the actuator, since the center land of the spool valve blocks the input port. The pressurized fluid flows through the alternate routes, through the two restrictors (labeled fixed orifices), passes through the two nozzles, and returns to the reservoir without causing any movement of the actuator.

If the right-hand solenoid is energized, the magnetic reed will move to the right, blocking off the flow of high-pressure fluid through the right-hand nozzle. Pressure will build up in the right-hand pressure chamber. This will move the valve to the left. In moving left, the center land will open the high-pressure inlet and permit fluid flow directly to the right-hand side of the actuator. At the same time, the left-hand land of the spool will open the low-pressure return line and permit flow through the return to the reservoir from the left-hand side of the actuator. This process will cause actuator movement to the left. By energizing the left-hand solenoid, the magnetic reed will move to the left, and the entire process will be reversed, the actuator then being moved to the right.

Note that the servo valve is basically a sliding spool valve. The servomechanism is just another method of control. This type valve has many applications in fluid power systems. For example, servo valves are used in the guidance systems of missiles and control systems of aircraft.

13079

13080

CHAPTER 12

ACTUATORS

One of the outstanding features of fluid power systems is that force, generated by the power supply, controlled and directed by suitable valving, and transported by lines, can be converted with ease to almost any kind of mechanical motion desired at the very place it is needed. Linear or rotary motion can be obtained by using a suitable actuating device.

An actuator is a device which converts fluid power into mechanical force and motion. Cylinders, motors, and turbines are the most common types of actuating devices used in fluid power systems.

The first part of this chapter is devoted to the various types of actuating cylinders and their applications in fluid power systems. The next part of the chapter covers the different types of fluid motors used in fluid power systems. The remainder of the chapter covers air turbines and turbine governors.

CYLINDERS

An actuating cylinder is a device which converts fluid power to linear or straight line force and motion. The cylinder consists of a movable element, such as a ram or piston, operating within a cylindrical bore. Actuating cylinders are normally installed in such a manner that the movable element is attached to the mechanism to be operated and the cylinder is anchored to a stationary structure. However, in some applications, the piston or ram is anchored to the stationary structure, and the cylinder is attached to the mechanism to be operated and becomes the movable part of the actuator.

Leakage of fluid out of the ends of the cylinders and around the circumference of the piston or ram is controlled by suitably designed seals and packings.

Actuating cylinders for pneumatic and hydraulic systems are similar in design and operation. Some of the variations of ram and piston type actuating cylinders are described in the following paragraphs.

RAM TYPE CYLINDERS

Although the terms ram and piston are often used interchangeably, a ram type cylinder is usually considered one in which the cross-sectional area of the piston rod is more than one-half the cross-sectional area of the movable element. In many cylinders of this type, the rod and movable element have equal areas. The ram type actuating cylinder is used primarily for push functions rather than pull.

Some applications of the ram type cylinder require simply a flat surface on the external part of the ram for pushing or lifting the unit to be operated. Other applications require some mechanical means of attachment, such as a clevis or eyebolt.

Single-Acting Ram

The single-acting ram applies force in only one direction. (See fig. 12-1.) Fluid directed into the cylinder displaces the ram and forces it outward. Since there is no provision for retracting the ram by the use of fluid power, the retracting force can be gravity, or some mechanical means, such as a spring. This type actuating cylinder is often used in the hydraulic jack. Fluid pressure is used to force the ram outward and lift an object. When fluid pressure is released, the weight of the object (gravity) forces the ram down, which, in turn, forces the fluid back to the reservoir.

Double-Acting Ram

A double-acting ram type cylinder is illustrated in figure 12-2. In this type cylinder both

13080

Figure 12-1.—Single-acting ram type actuating cylinder.

Figure 12-2.—Double-acting ram type actuating cylinder.

strokes of the ram are produced by pressurized fluid. Fluid under pressure is directed to the bottom of the cylinder which extends the ram and applies force. To retract the ram and reduce force, fluid is directed to the top of the cylinder.

A four-way directional control valve is normally utilized to control the double-acting ram. When the valve is positioned to extend the ram, pressurized fluid enters port (A), acts on the bottom surface of the ram, and forces the ram outward. Fluid above the ram lip is free to flow out of port (B), through the control valve and to return/exhaust.

When the directional control valve is positioned to retract the ram, pressurized fluid enters port (B) and acts on the top surface of the ram lip, forcing the ram down. The fluid from the bottom of the cylinder is free to flow out of port (A) and through the directional control valve to return/exhaust.

Normally, the pressure of the fluid is the same for either stroke of the ram. However, note the difference of the areas upon which the pressure acts. The pressure acts against the large surface area on the bottom of the ram during the extension stroke, at which time the ram applies force. Since the ram does not apply force during the retraction stroke, pressure acting on the small area on the top surface of the ram lip provides the necessary force to retract the ram.

Telescoping Cylinders

Figure 12-3 shows a telescoping ram type actuating cylinder. A series of rams is nested in the telescoping assembly. With the exception of the smallest ram, each ram is hollow and serves as the cylinder housing for the next smaller ram. The ram assembly is contained in the main cylinder housing which also provides the fluid ports. Although the assembly requires a small space with all of the rams retracted, the telescoping action of the assembly provides a relatively long stroke when the rams are extended.

An excellent example of the application of this type cylinder is in the dump truck. It is used to lift the forward end of the truck bed and dump the load. A greater force is required for the initial lifting of the load. As the load is lifted and begins to dump, the required force becomes less and less until the load is completely dumped. In the raise position, pressurized fluid enters the cylinder through port (A) and acts on the bottom surfaces of all three rams. (See fig. 12-3.) Ram (1) has the largest surface area, and therefore, provides the greater force for the initial load. As ram (1) reaches the end of its stroke and the required force decreases,

SECRET
13081

Figure 12-3.-Telescoping ram type actuating cylinder.

ram (2) moves, providing the lesser force needed to continue raising the load. When ram (2) completes its stroke, a still lesser force is required. Ram (3) then moves outward to finish raising and dumping the load.

Some telescoping cylinders are of the single-acting type. In this type the rams are retracted by gravity or mechanical force. Others, like the one illustrated in figure 12-3, are of the double-acting type. In this type, fluid pressure is utilized for both the extension and retraction strokes. A four-way directional control valve is commonly used to control the operation of the double-acting type. Note the small passages in the walls of rams (1) and (2). They provide a path for the fluid to flow to and from the chambers above the lips of rams (2) and (3). During the extension stroke, return fluid flows through these passages and out of the cylinder through port (B). It then flows through the directional control valve to return/exhaust.

To retract the rams, fluid under pressure is directed into the cylinder through port (B) and acts against the top surface areas of all three ram lips. This forces the rams to the retracted position. The displaced fluid from the opposite side of the rams flows out of the cylinder through port (A), through the directional control valve to return/exhaust.

Dual Rams

A dual ram assembly is illustrated in figure 12-4. This assembly consists of a single ram

Figure 12-4.—Dual ram actuating cylinder.

with a cylinder at either end. Fluid can be directed to either cylinder, forcing the ram to move in the opposite direction. The ram is connected through mechanical linkage to the unit to be operated. A four-way directional control valve is commonly used to operate the dual ram. When the control valve is positioned to direct fluid under pressure to one of the cylinders, for example the left, the ram is forced to the right. This action displaces the fluid in the opposite cylinder. This displaced fluid flows back through the directional control valve to return/exhaust.

Dual ram actuating cylinders are used in the steering systems of most ships. In some systems one assembly is utilized to actuate the rudder in either direction; while in other systems, two assemblies are used for the same purpose. (These steering systems are described and illustrated in chapter 13.)

PISTON TYPE CYLINDER

An actuating cylinder in which the cross-sectional area of the piston rod is less than one-half the cross-sectional area of the movable element is referred to as a piston type cylinder. The piston type cylinder is normally used for applications which require both push and pull functions. Thus, the piston type serves many more requirements than the ram type and, therefore, is the most common type utilized in fluid power systems.

The housing consists of a cylindrical barrel which usually contains either external or internal threads on both ends. End caps with mating threads are attached to the ends of the cylinder. The end caps usually contain the fluid ports. The end cap on the rod end contains a hole for the piston rod to pass through. Suitable packing must be used between the hole and the piston rod to prevent external leakage. The opposite end cap of most cylinders is provided with a fitting for securing the actuating cylinder to

13082

some structure. For obvious reasons, this end cap is referred to as the anchor end cap.

The piston rod may extend through either or both ends of the cylinder. The end of the rod is normally threaded for the attachment of some type of mechanical connector, such as an eyebolt or a clevis, and a locknut. This threaded connection of the rod and clevis provides for adjustment between the rod and the unit to be actuated. After correct adjustment is obtained, the locknut is tightened against the clevis to prevent it from turning. The other end of the clevis or eyebolt is connected, either directly or through additional mechanical linkage, to the unit to be actuated.

In order to satisfy the many different requirements of fluid power systems, piston type cylinders are available in various designs. Some of the most common designs are described in the following paragraphs.

Single-Acting

The single-acting piston type cylinder utilizes fluid pressure to apply force in only one direction. In some designs of this type, the force of gravity moves the piston in the opposite direction. However, most cylinders of this type apply force in both directions. Fluid pressure provides the force in one direction and spring tension provides the force in the opposite direction.

Figure 12-5 illustrates a single-acting, spring-loaded piston type actuating cylinder. In this cylinder the spring is located on the rod side of the piston. In some spring-loaded cylinders the spring is located on the blank side and the fluid port is on the rod end of the cylinder.

A three-way directional control valve is normally used to control the operation of this cylinder. To extend the piston rod, fluid under pressure is directed through the port and into the cylinder. (See fig. 12-5.) This pressure acts on the surface area of the blank side of the piston, extending the rod to the right through the end of the cylinder. At the same time, the spring is compressed between the rod side of the piston and the end of the cylinder. Within limits of the cylinder, the length of the stroke depends on the desired movement of the actuated unit.

To retract the piston rod, the directional control valve is moved to the opposite working position which releases the pressure in the cylinder. The spring tension forces the piston to the left, retracting the piston rod. The fluid is

Figure 12-5.—Single-acting, spring-loaded piston type actuating cylinder.

free to flow from the cylinder through the port, back through the control valve to return/exhaust.

The side of the piston opposite the fluid port is vented to the atmosphere. This prevents air from being trapped in this area. Any trapped air would compress during the extension stroke, creating excess pressure on the rod side of the piston. This would cause sluggish movement of the piston and could eventually cause a complete lock, preventing the fluid pressure from moving the piston.

Leakage between the cylinder wall and the piston is prevented by adequate seals. The piston in figure 12-5 contains V-ring seals. (Note that the V's of the seals are placed toward the fluid pressure.) V-rings are used in some cylinders; however, O-rings are utilized in most piston type cylinders.

The spring-loaded cylinder is often used to actuate the arresting hook on carrier aircraft. Raising the arresting hook occurs when fluid pressure is applied through the arresting hook control valve to the fluid side of the piston. This force moves the piston, which through the rod and mechanical linkage, raises the hook. This same force compresses the spring. The arresting hook extends when fluid pressure is relieved and the spring expands.

Double-Acting

Most piston type actuating cylinders are double-acting which means that fluid under pressure can be applied to either side of the piston to provide movement and apply force in the corresponding direction.

One design of the double-acting piston type cylinder is illustrated in figure 12-6. This cylinder operates under the influence of fluid flow in either direction. The cylinder contains one piston and piston rod assembly. The two fluid ports, one near each end of the cylinder, alternate as inlet and outlet, depending on the

A8061 13083

Figure 12-6.—Double-acting piston type actuating cylinder.

direction of flow from the directional control valve.

This is an unbalanced actuating cylinder; that is, there is a difference in the effective working areas on the two sides of the piston. Assume that the cross-sectional area of the piston is 3 square inches and the cross-sectional area of the rod is 1 square inch. In 2,000-psi systems, pressure acting against the blank side of the piston creates a force of 6,000 pounds (2,000 x 3). The 2,000 psi acting against the rod side of the piston creates a force of 4,000 pounds (2,000 x 2). For this reason, this type cylinder is normally installed in such a manner that the blank side of the piston carries the greater load; that is, the cylinder carries the greater load during the piston rod extension stroke.

A four-way directional control valve is normally used to control the operation of this type cylinder. The valve can be positioned to direct fluid under pressure to either end of the cylinder and allow the displaced fluid to flow from the opposite end of the cylinder through the control valve to return/exhaust.

The piston of the cylinder illustrated in figure 12-6 is equipped with an O-ring to prevent internal leakage of fluid from one side of the piston to the other. Some cylinders of this type have a felt wiper-ring attached to the inside of the end cap and fitted around the piston rod to guard against the entrance of dirt into the cylinder. In some localities the atmosphere contains a large amount of dust and abrasive particles. These particles are very harmful to the smooth surface of the piston rod. To prevent damage from these particles, cylinders used in such localities are often equipped with flexible, synthetic rubber, protective coverings around the exposed end of the rod. This covering is referred to as a boot.

Figure 12-7 illustrates a three-port, double-acting piston type actuating cylinder. This type is used in applications where it is necessary to move two mechanisms at the same time. This cylinder contains two pistons and piston rod assemblies.

Fluid under pressure is directed through port (A) by a four-way directional control valve and moves the pistons outward, thus moving the mechanisms attached to the two piston rods. The fluid on the rod side of each piston is forced out of the cylinder through ports (B) and (C) which are connected by a common line to the directional control valve. The displaced fluid then flows through the control valve to return/exhaust.

When fluid under pressure is directed into the cylinder through ports (B) and (C), the two pistons move inward, and the mechanisms to which the piston rods are attached are moved accordingly. Fluid between the two pistons is free to flow through port (A) and through the control valve to return/exhaust.

The actuating cylinder illustrated in figure 12-8 is a double-acting balanced type. The piston rod extends through the piston and out through both ends of the cylinder. One or both of these rods may be attached to a mechanism. In either case, the cylinder provides equal areas on each side of the piston so that the amount of fluid and force required to move the piston a

Cotton Verticillium Wilt

By Ivan J. Shields
Extension Plant Pathologist

The severity of Verticillium wilt has varied from season to season and from soil to soil in Arizona cotton fields. All cotton areas in Arizona have this disease. The greatest losses are being experienced in the Tucson, Safford, Elfrida and Duncan areas. Rapid increase in cotton losses have occurred in the Marana, Casa Grande, Eloy, Florence and Phoenix areas. Once the disease is present, it is soon scattered over the field. (See Figure 1)

Figure 1. Scattered Verticillium wilt infected cotton is evident in a field near Beardsley, Arizona. Infected plants and gin trash carry the fungus over to next season.

WHAT'S YOUR LOSS?

Look for this disease in your cotton fields. Verticillium wilt causes a definite mottling of leaves with pale yellowish areas on the margins and between the veins. As the disease progresses, the yellow areas in the leaf turn brown. The lower leaves are the first to fall. When cotton plants are infected early they may be stunted or killed. (See Figure 2)

Figure 2. Stunted or dead cotton plants result from early infection by this soil-borne fungus. Healthy and diseased plants are of the variety Delta Pine.

CHECK THE STEM

Shortly after infection, the cotton plants will show brownish streaks in the stem. (See Figure 3) Later these streaks

Figure 3. Streaked, brown discolored stems are evident in cotton infected with Verticillium wilt.

Cooperative Extension Service and Department of Plant Pathology of the Agricultural Experiment Station, The University of Arizona, Tucson

certain distance in one direction is exactly the same as the amount required to move it an equal distance in the opposite direction. This type cylinder is commonly used in servomechanisms.

Like the unbalanced, double-acting cylinders, both the three-port and balanced cylinders require suitable seals around the pistons and suitable packing around the piston rods. These cylinders may also be equipped with protective boots around the exposed piston rod.

Cushioned Cylinders

In order to slow the action and prevent shock at the end of the piston stroke, some actuating cylinders are constructed with a cushioning device at either or both ends of the cylinder. This cushion is usually a metering device built into the cylinder to restrict flow at the outlet port, thereby slowing down the motion of the piston. There are various designs used to provide this cushioning effect. One such design is shown in the actuating cylinder illustrated in figure 12-9.

In the cylinder illustrated in figure 12-9, the piston movement is cushioned near the end of the extension stroke. As fluid under pressure flows into port (A), it acts against the blank side of the piston, forcing the piston and rod to the right. Fluid from the rod side of the piston is free to flow between the center hole of the cushioning element and out port (B). Some fluid flows through the metering orifice, but spring tension and fluid pressure cause the check valve to seat, blocking flow through this point. This action continues until the raised portion of the piston rod reaches the center hole of the cushioning element. The close tolerance between this portion of the rod and the center hole results in near stoppage of flow around the piston rod. The remainder of the fluid must flow through the metering orifice. This reduced volume of flow offers resistance to the moving piston, thus cushioning the end of the piston stroke.

Figure 12-9.—Cushioned actuating cylinder.

To actuate the cylinder in the opposite direction, fluid under pressure is directed into the cylinder through port (B). This pressure overcomes spring tension and unseats the check valve. This allows an unrestricted flow into the cylinder and forces the piston to move to the left.

LIMITED ROTATION CYLINDERS

Rotary actuation of fluid power equipment is normally provided by fluid power motors. However, certain actuating cylinders are designed to provide limited rotary actuation. The rotation is normally limited to approximately 280 degrees. Like all fluid power components, there are many different designs of limited rotation cylinders. One design of this type cylinder is illustrated in the hydraulic windshield wiper system shown in figure 12-10. The design is often referred to as the rack and pinion actuator.

The windshield wiper must move back and forth in an arc of approximately 180 degrees. The rack and pinion actuator provides this limited rotation. The wiper has a mechanical oscillating device which changes the fluid flow to opposite ends of the rack and pinion actuator. The piston rod contains a piston on either end. Motion is caused by the movement of the piston rod which has teeth (serrations) machined along one side. These serrations (the rack) mesh with a gear (the pinion) which has teeth around only a portion of its circumference. As the piston moves back and forth, it causes the rotary motion of the shaft to which the gear is attached. The windshield wiper is attached to the opposite end of the gear shaft.

Only a few of the many applications of actuating cylinders are discussed in the preceding paragraphs. Figure 12-11 illustrates additional types of force and motion applications obtainable. To meet the various requirements of fluid power systems, actuating cylinders are available in many different shapes and sizes.

In addition to its versatility, the cylinder type actuator is probably the most trouble-free component of fluid power systems. It is very important that the cylinder and the mechanical members of the unit to be actuated are correctly aligned. Any misalignment will cause excessive wear of the piston, piston rod, and seals. Also, proper adjustment between the piston rod and the

13088

Figure 12-10.—Application of limited rotation actuating cylinder.

actuating unit must be maintained. The exposed ends of the piston rods must be cleaned as required to guard against the entrance of foreign matter into the cylinder.

MOTORS

A fluid power motor is a device which converts fluid power energy to rotary motion and force. Basically, the function of a motor is just the opposite as that of a pump. However, the design and operation of fluid power motors are very similar to pumps. In fact, many hydraulic pumps can be used as motors with little or no modifications. Therefore, a thorough knowledge of the pumps described in chapter 7 will be extremely helpful for understanding the operation of fluid power motors.

Motors serve many applications in fluid power systems. In hydraulic power drives, pumps and motors are combined with suitable lines and valves to form hydraulic transmissions. The pump, commonly referred to as the A-end, is driven by some outside source, such as an electric motor. The pump delivers fluid to the fluid motor. The motor, referred to as the B-end, is actuated by this flow, and through mechanical linkage, conveys rotary motion and force to the work. This type power drive is used to operate (train and elevate) many of the Navy's guns and rocket launchers. Air motors are used in missiles to convert the potential energy of compressed air into electric power, or to drive the pump of the hydraulic system. These are only a few of applications of fluid power motors.

Fluid motors are generally rated in terms of displacement and torque. Displacement refers to the amount of fluid necessary to force the motor through one complete cycle. Displacement is expressed in cubic inches or gallons per minute. The torque (twisting or rotating force) is expressed in inch-pounds at a certain pressure.

The output speed and torque of the motor depends on the power input in terms of pressure and rate of flow. The output speed is proportional to the input volume. The ratio between these two factors depends on the displacement of the motor. The pressure difference between the inlet and outlet ports and the mechanical efficiency of the motor determine the output torque.

The speed and torque requirements vary in different applications. In some applications the unit must be actuated at a high speed, while very little torque is required for the operation. In other applications, low speed and high torque are required to operate a particular unit. The requirements of most applications vary between these two extremes. The ratio of these two factors—speed and torque—depends on the displacement of the motor. With input flow and pressure remaining constant, a decrease in displacement increases the speed of the motor but reduces the torque proportionally. In other words, the decrease in displacement reduces the amount of fluid required for each cycle of the motor element. Thus, with the same rate of flow, the motor element completes more cycles per volume of fluid. However, this reduced volume of fluid decreases the force acting on the motor element, thus reducing the torque. An increase in displacement requires a larger volume of fluid for each cycle, thus reducing the

13086

Figure 12-11.—Applications of actuating cylinders.

12087

speed of the motor. The larger volume of fluid increases the force acting on the motor element, thus increasing torque.

Fluid motors may be of the fixed displacement or variable displacement type. The fixed displacement provides constant torque and variable speed. The speed is varied by controlling the amount of input flow. The variable displacement motor is constructed in a manner which permits the working relationship of the internal parts to be varied so as to change displacement. This provides variable torque and variable speed. With input flow and operating pressure remaining constant, the ratio between torque and speed can be varied to meet load requirements by varying displacement. The majority of the motors used in fluid power systems are of the fixed displacement type.

Although most fluid power motors are capable of providing rotary motion in either direction, some applications require rotation in only one direction. In these applications one port of the motor is connected to the system pressure line and the other port to return or exhaust. The flow of fluid to the motor may be controlled by a flow control valve (ON and OFF valve), a two-way directional control valve, or by starting and stopping the power supply; for example, the pump in a hydraulic system. The speed of the motor may be controlled by varying the rate of flow. This can be accomplished by incorporating a flow control valve (restrictor or flow regulator) in the pressure supply line. In many hydraulic systems, the rate of flow is controlled by varying the output of the variable displacement pump.

In most hydraulic systems the motor is required to provide actuation in either direction. In these applications the ports are referred to as working ports, alternating as inlet and outlet ports. The flow to the motor is usually controlled by either a four-way directional control or a variable displacement pump.

Fluid power motors are usually classified according to the type of internal element, which is directly actuated by the flow. The most common types of elements are the gear, vane, and piston. All three of these types are adaptable for hydraulic systems, while only the vane type is utilized in pneumatic systems.

GEAR TYPE

The gears of the gear type motor are of the external type and may be of the spur, helical, or herringbone design. The operation of a gear type motor is illustrated in figure 12-12. Both gears are driven gears; however, only one is connected to the output shaft. As fluid under pressure enters chamber (A), it takes the path of least resistance and flows around the inside surface of the housing, forcing the gears to rotate as indicated. The flow continues through the outlet port to return. This rotary motion of the gears is conveyed through the shaft to the work unit.

Although the motor is illustrated in figure 12-12 shows operation in only one direction, the gear type motor is capable of providing rotary motion in either direction. The ports alternate as inlet and outlet. To reverse the direction of rotation, the fluid is directed through the port labeled outlet into chamber (B). The flow through the motor rotates the gears in the opposite direction, thus actuating the work unit accordingly.

VANE TYPE

A typical vane type air motor is illustrated in figure 12-13. This particular motor provides rotation in only one direction. It operates on the principle of differential areas. The motor consists of a slotted rotor which is mounted on a drive shaft. Each slot of the rotor is fitted with a freely sliding rectangular vane. The rotor and vanes are enclosed in the housing, the inner surface of which is offset with the drive shaft axis. When the rotor is in motion, the vanes tend to slide outward due to centrifugal force. The distance the vanes slide is limited by the shape of the rotor housing.

Figure 12-12.—Gear type motor.

180-13088

Figure 12-13.—Vane type air motor.

Figure 12-14.—Vane type motor.

When compressed air is ported into the inlet port, its pressure is exerted equally in all directions. Since area (A) is greater than area (B), the rotor will turn counterclockwise. Each vane in turn assumes the No. 1 and No. 2 position and the rotor turns continuously. The potential energy of the compressed air is thus converted into kinetic energy in the form of rotary motion and force. The air at reduced pressure is exhausted to the atmosphere. The shaft of the motor is connected to the unit to be actuated.

Many vane type motors are capable of providing rotation in either direction. A motor of this design is illustrated in figure 12-14. The principle of operation is the same as the vane type motor previously described. The two ports may be alternately used as inlet and outlet, thus providing rotation in either direction. Note the springs in the slots of the rotor. Their purpose is to hold the vanes against the housing during the initial starting of the motor, since no centrifugal force exists until the rotor begins to rotate. Springs are not required in vane type pumps because the drive shaft provides the initial centrifugal force.

PISTON TYPE

Like piston (reciprocating) type pumps, the most common designs of piston type motors are the radial and axial. As previously stated, piston type motors are adaptable only to hydraulic systems.

Although some piston type motors are controlled by directional control valves, they are often used in combination with variable displacement pumps. This pump-motor combination (hydraulic transmission) is used to provide a transfer of power between a driving element, for example an electric motor, and a driven element. Some of the applications for which hydraulic transmissions may be used are speed reducer, variable speed drive, constant speed or constant torque drive, and torque converter. Some advantages of hydraulic transmission over mechanical transmission of power are as follows:

1. Quick, easy speed adjustment over a wide range while the power source is operating at constant (most efficient) speed. Rapid, smooth acceleration or deceleration.
2. Control over maximum torque and power.
3. Cushioning effect to reduce shock loads.
4. Smooth reversal of motion.

(While studying the description of piston type motors in the following paragraphs, it may be necessary to refer to chapter 7 for a review of the operation and particularly the parts of the radial and axial piston pumps.)

Radial

Figure 7-17 in chapter 7 shows a view of the radial piston pump or motor and identifies the parts. In the radial piston pump, as the cylinder block revolves, the pistons press against the rotor and are forced in and out of the

0003089

cylinder, thereby receiving fluid and pushing it out into the system. The motor operates in reverse--fluid forced into the cylinder drives the pistons outward. The pistons pushing against the rotor cause the cylinder block to revolve.

The operation of a radial piston motor is illustrated in figure 12-15. For simplicity, only three pistons are shown. If liquid is introduced into the cylinder (1), the piston must move outward since the liquid cannot be compressed and two bodies cannot occupy the same space. To allow for this movement the cylinder block must revolve in a clockwise direction, since the piston, in moving out, will seek the point of greatest distance between the cylinder block and the rotor. As the force acting on piston (1) causes the cylinder block to move, piston (2) starts to change position and will approach the position of piston (3). It should be noted that the distance between the cylinder block and the reaction ring of the rotor gets progressively shorter on the top half of the rotor as is shown in figure 12-15. As piston (2) moves, it is forced inward and in turn forces the liquid out of the cylinder. Since there is little or no pressure on this side of the pintle valve, the piston is easily moved in by the contact with the reaction ring of the rotor. The liquid is easily forced out of the cylinder and back to a reservoir or to the inlet side of the pump. As piston (3) moves past the midpoint, or past the shortest distance between the cylinder block and rotor, it enters the pressure side of the pintle valve and liquid is forced into the cylinder. Piston (3) then becomes the pushing piston and in turn rotates the cylinder block. This action continues as long as liquid under pressure enters the cylinders. The rate at which the liquid flows into the cylinders determines the speed at which the cylinder block turns.

As a hydraulic transmission, the two ports of the motor are connected to the two ports of the pump. To control the motor speed, it is necessary to control the output capacity of the pump. This is accomplished by controlling the degree to which the slide block of the pump is offcenter in relation to the center of the cylinder block. Pressure in the system is practically independent of the volume output of the pump, and thus the speed of the motor, but varies with the load on the output shaft of the motor.

Assume that in a pump-motor combination of this type, in which both units are the same size, the rotor is set offcenter in the pump a distance that is just equal to the offset of the rotor in the motor. For each full discharge of one cylinder in the pump, a piston in the motor must move an equal distance, as it receives the same amount of liquid that the pump discharges. The cylinder block of the motor revolves at the same speed as the cylinder block of the pump. Now assume that the offset distance in the pump is shortened, so that it requires the discharge of two cylinders in the pump to fill one cylinder in the motor. Under this condition the cylinder block of the pump completes two revolutions for each revolution of the cylinder block in the motor. Thus, the motor rotates at just half the speed of the pump.

Figure 12-15.—Operation of radial piston motor.

Since the operator has a wide control over the pump end, he has an equal control over the motor end—a control achieved by regulating the amount of flow from the pump. If, in the pump, the rotor and cylinder block are centered, no pumping action will take place, consequently no liquid will be delivered to the motor end, and therefore the output shaft of the motor will not rotate.

In the pump, the direction of flow is reversed by moving the rotor from one side of the neutral position to the other. In the motor, the position of the rotor is fixed. Action of the motor is reversed, however, by reversing the output of the pump. Thus, liquid enters the motor on the top side of the pintle valve, which causes cylinder (3) (fig. 12-15) to become the cylinder into which liquid enters under pressure. This forces the cylinder block to rotate in the opposite direction.

e8013090

Variable displacement radial piston motors are available for applications where variable torque is required. If constant speed is required in these applications, a constant displacement pump is used. If control of both speed and torque is required, both the pump and the motor are of the variable displacement type.

Axial Piston

One design of the axial piston type motor is illustrated in figure 12-16. This motor is identical in design to the constant displacement axial piston pump. The operation of this type motor is similar to the operation of the radial piston motor. Fluid under pressure flows through one of the ports in the valve plate and enters the bores of the cylinder block that are open to the port. (For example, in a nine piston motor, four cylinder bores are receiving fluid while four are discharging.) The fluid acting on the pistons in these bores forces the pistons to move away from the valve plate. Since the pistons are held by connecting rods at a fixed distance from the output shaft flange, they can move away from the valve plate only by moving in a rotary direction. The pistons move in this direction to a point around the shaft axis which is the greatest distance from the valve plate. Therefore, driving the pistons axially causes them to rotate the drive shaft and cylinder block. While some of the pistons are being driven by liquid flow from the system, the remaining ones are discharging flow from the outlet port.

Figure 12-16.—Axial piston hydraulic motor.

This type motor may be operated in either direction of rotation, the rotation being controlled by the direction of flow to the valve plate ports. The direction of flow may be instantly reversed without damage to the motor.

This design of axial piston motors is commonly used in aircraft hydraulic systems to operate such components as landing flaps and radar equipment. In these applications the direction of flow is controlled by four-way directional control valves.

Figure 12-17 shows a hydraulic transmission consisting of an axial piston pump and motor

Figure 12-17.—Hydraulic transmission.

13091

combination. The A-end is a variable displacement axial piston pump. The motor (B-end) is identical to the pump except that it is of the fixed displacement type. Although of slightly different design, the operation of the motor is very similar to the axial piston motor just described.

The hydraulic motor or B-end can be directly connected hydraulically to the pump as illustrated in figure 12-17, or the motor can be installed at a distance from the pump with the two mechanisms connected by piping.

The speed of rotation of this unit is controlled in the same manner as the radial piston unit. With each full stroke of a pump piston, a motor piston must move an equal distance. Thus, speed of output equals speed of input. If the tilting plate (box) of the pump is changed so that the piston stroke of the pump is only one-half as long as the stroke of the motor, it will require the discharge from two pump cylinders to fill one motor cylinder. The motor will then revolve just one-half as fast as the pump. If there is no tilt on the tilting plate, the pumping pistons will not move axially, and no liquid will be delivered to the motor. Therefore, the motor will deliver no power.

If the tilting plate of the pump is reversed, the direction of flow is reversed. Liquid enters the motor through the port by which it formerly was discharged. This reverses the direction of rotation of the motor. The motor rotates in the same direction as the pump when the two tilting plates are tilted in the same direction, and in the opposite direction when the two are tilted oppositely.

Some applications require a wide range of torque variation. Variable displacement motors are available for these applications. Like the radial piston combination, the variable displacement axial piston motor may be controlled by either a fixed or a variable displacement pump.

TURBINES

Another device used for converting fluid power energy into rotary force and motion is the turbine. Turbines are commonly used in pneumatic systems for this purpose. For example, an air turbine may be used to drive an electric generator, thus converting the potential energy of compressed gas into electrical power. A turbine may also be used to drive the pump and supply fluid flow in a hydraulic system. Some of the most common types of air turbines are described in the following paragraphs.

PINWHEEL TURBINE

One type of air turbine is the pinwheel turbine shown in figure 12-18. This turbine is a mechanical jet, similar in principle to a garden sprinkler. Compressed gas is led into the pinwheel hub through the hollow shaft. It eventually passes through the diametrically opposed nozzles where its velocity is increased. (See Bernoulli's principle in chapter 2.) The reaction to the exhaust causes rotation of the pinwheel. The amount of reaction (thrust) is equal to the force of the escaping gas. This force can be determined by measuring the volume and velocity of the gas which escapes. The shaft of the air turbine is connected to the unit to be operated.

Figure 12-18.—Pinwheel turbine.

MULTIPLE-STAGE TURBINE

A multiple-stage turbine is illustrated in figure 12-19. The turbine wheel is a solid piece of steel having semicircular recesses (buckets) cut into the surface of its outside circumference. Mounted on the casing around the wheel are four nozzles spaced 90 degrees apart. Within the casing are a series of stationary semicircular reversing chambers. The compressed gas is led through a gas manifold ring and passes through the nozzles. The gas then impinges at high velocity on the buckets. In passing through the buckets the direction of flow is reversed 180 degrees. The gas is then caught by a semicircular reversing chamber

13092

Figure 12-19.—Multiple-stage turbine.

in the casing where it is again reversed 180 degrees and returned to the wheel. The process is repeated five times through a 90-degree arc of the turbine housing after which the gas is exhausted. Reversing the flow of gas several times gives a multiple-stage effect, thereby using more of the potential energy in the gas.

SINGLE-STAGE TURBINE

Another type of turbine is the single-stage turbine shown in figure 12-20. In this turbine the gas expelled through the nozzles is not reversed in direction, but makes only one pass through the turbine.

TURBINE GOVERNORS

As mentioned previously, turbines are often coupled to electric generators. To provide a constant electric output, a governor is commonly used to control turbine speed within very close tolerances. Several types of turbine governors are described in the following paragraphs.

Figure 12-20.—Single-stage turbine.

Moving Shutter Governor

The moving shutter governor is used to control the speed of the pinwheel turbine. It is mounted in the hub of the pinwheel, as shown in figures 12-21 (A) and 12-21 (B). Compressed gas entering the turbine through the follow shaft must pass through the governor before it can pass through the jet nozzles. The governor consists of a shutter secured to a torsion bar. (See fig. 12-21 (C).) As the turbine rotates, centrifugal force causes the shutter to attempt to align itself in the plane of turbine rotation. In figure 12-21 (B) the shutter tends to turn clockwise and block the flow of gas to the nozzles. The torsion bar restrains the shutter from blocking the outlets. As turbine speed approaches a specified limit, the force on the shutter begins to overcome the resistance of the torsion bar, thus permitting the shutter to turn clockwise and partially block the outlets to maintain speed at the specified limit. If turbine speed decreases, the torsion bar overcomes the centrifugal force, and the shutter moves counterclockwise to uncover the outlets. Thus, the moving shutter governor continuously controls turbine speed by metering the flow of gas to the nozzles.

Flyball Governor

A very common type of turbine governor is the flyball governor illustrated in figure 12-22.

SCCGI 13093

Figure 12-21.—Moving shutter governor.

The coiled springs provide a restraining force on a pair of pivoted counterweights mounted on the turbine shaft. When shaft speed reaches design speed, centrifugal force overcomes spring tension. The counterweights pivot, causing the brake shoes to bear on the brake drum. When design speed is exceeded, the centrifugal force and the braking action increase. At decreasing speeds, the centrifugal force lessens, and the braking action decreases. Thus, a constant turbine speed is maintained.

Another type of flyball governor controls turbine speed by metering the flow of gas to the turbine. Its springs and counterweights are coupled to a valve on the input side of the turbine. Centrifugal force causes the weights to open and close the valve, thereby controlling turbine speed.

Figure 12-22.—Flyball governor.

18033
10004

may completely darken the wood. The progress of the disease will slow down during high summer temperatures and the plant will return to normal growth. During this period, no symptoms will show on the leaves and new wood of the stem will be normal. The disease becomes active again in the fall with the return of cooler temperatures.

PREVENT THE SPREAD

Disease readily spreads as diseased plant parts are scattered. Certain practices of precaution should be exercised.

1. Plant seed free of trash, as diseased leaf and stem parts will carry the fungus. Verticillium may be carried on but not in cotton seed.

2. Plow under crop residues immediately after harvest.

3. Refrain from spreading gin trash on fields as most gin trash in Arizona will be infested with Verticillium wilt.

REDUCE LOSSES BY

1. Follow a crop rotation.

Other crops not susceptible to Verticillium wilt will slow the build-up of the disease. Potato, tomato, cantaloup, sugar beet, safflower and flax are susceptible and should not be used in rotation.

2. Do not over-irrigate.

Use no more water than necessary for cotton production, since water lowers the soil temperature thus favors the wilt fungus.

3. Try dry summer fallow.

Tests in wilt areas have shown this to be beneficial in reducing the disease.

4. Control Weeds.

Ten weeds commonly found in Arizona cotton fields have been found as hosts for wilt.

5. Plant tolerant varieties.

Arizona WR-44 and California 442 are tolerant to Verticillium wilt. Delta Pine and A-44 are quite susceptible. The long staple cottons are more tolerant than short staple types.

RESEARCH IN PROGRESS IN ARIZONA

Selections from cotton varieties which were highly tolerant to Verticillium wilt were made several years ago. These selections have been screened and some are now being grown in preliminary yield test. Most of the tests are at The University of Arizona Experiment Farm near Marana. Research workers from U of A and A.R.S. are working cooperatively on these tests.

CHAPTER 13

HYDRAULIC AND PNEUMATIC SYSTEMS

Some of the different applications of fluid power are mentioned throughout this course. These examples indicate, to some extent, that many different designs of systems are necessary to satisfy the requirements of fluid power applications. The type, quantity, and combination of components vary in fluid power systems. Systems range from the simple hydraulic jack described in chapter 4 to extremely complex systems, some of which combine the use of pneumatics and hydraulics.

A few typical systems are described in this chapter to show some of the different applications of fluid power in the Navy. It must be stressed that these are representative systems and not specific systems. Applicable technical publications should be consulted for the operation, servicing, and maintenance of specific systems used in actual applications.

The systems are covered in the following order:

1. Hydraulic power drive.
2. Electrohydraulic steering.
3. Missile fluid power systems.
4. Aircraft fluid power systems.

HYDRAULIC POWER DRIVE SYSTEM

The hydraulic power drive has been used in the Navy for many years. Proof of its effectiveness is the fact that it has been used to train (provide horizontal movement) and elevate (provide vertical movement) nearly all calibers of guns, from the 40-mm to the 16-inch turret. Modifications of these drives are currently being used for the operation of rocket launchers.

Although the power drive system described in this section is of the type used to operate gun mounts and rocket launchers, similar electrohydraulic drive units are used for driving and controlling such equipment as windlasses, capstands, and winches.

In its simplest form the hydraulic power drive consists of the following:

1. A prime mover. This is an electric motor which drives a hydraulic pump.

2. The A-end (hydraulic pump), driven by the electric motor. Its fluid output drives a hydraulic motor called the B-end.

3. The B-end. The output of the B-end is directly connected to the mount by mechanical gearing and shafting. While the A-end is driven at a constant speed by the electric motor, its output is variable. By controlling the output of the A-end, the direction and speed of the B-end, and, hence the direction and speed of the motion of the mount, can be controlled.

4. A means of introducing a signal to the A-end to control its output.

5. The mechanical shafting and gearing that transmits the B-end output to the train and elevation drive pinions.

The 5"/38 twin mounts are driven in train and elevation by separate hydraulic systems. As the systems differ only in size and minor details, only the train power drive is described in the following paragraphs.

The basic components of the train power drive are shown in figure 13-1. The electric drive motor is constructed with drive shafts at both ends. The forward shaft drives the A-end pump through reduction gears. The after shaft is coupled through reduction gears to the auxiliary pumps.

The ports in the A-end valve plate are connected to like ports in the B-end valve plate by large copper pipes. Fluid pumped by the A-end causes rotation of the B-end. Output of the B-end is connected by shafts and gears to the training circle of the gun mount. The function of each major component is described in the following paragraphs.

13095

Figure 13-1.—Train power drive-components.

ELECTRIC MOTOR

The prime mover, or electric drive motor, drives the A-end of the hydraulic power transmission. Through reduction gears, it also drives the replenishing pump, control pressure pump, and the sump pump and oscillator. A motor controller with associated pushbutton stations starts and stops the electric motor and gives protection against overload and overvoltage.

MAIN REDUCTION GEAR

The A-end pump is designed to operate at a speed of approximately 900 revolutions per minute. Since this speed is much lower than that of the electric motor, it is necessary to reduce the speed of rotation between the A-end and the electric motor. This speed reduction is accomplished through a gear reduction mechanism. The reduction gears are contained in a housing which is flange-mounted between the electric motor and the B-end. Also mounted on the motor drive shaft is a heavy flywheel, which tends to prevent any sudden change in the speed of reduction gear output.

HYDRAULIC TRANSMISSION

The hydraulic transmission system includes the following components:

1. A-end, an electrically driven variable displacement hydraulic pump.
2. Main cylinder, containing the stroke control shaft. (This assembly is used in controlling the tilt of the A-end.)
3. B-end, a fixed displacement hydraulic motor.
4. Auxiliary pumps.

A-End

The train A-end is an axial piston, variable displacement pump. The direction and speed of its output controls the direction and speed of rotation of the B-end. It is driven at a constant speed by the electric motor through the main reduction gears. The output is controlled by the tilt of the tilting box. Movement of the tilting box is directly controlled by the stroke control shaft.

13096

B-End

The B-end is similar in construction to the A-end except that the tilt of the tilting box is fixed; that is, the B-end is a fixed displacement motor. As the B-end pistons must each make a full stroke for every revolution of the output shaft, speed of the B-end and hence the speed at which the guns are trained (or elevated), is directly proportional to the angular displacement of the A-end tilting box from its neutral position.

The output shaft of the B-end motor is connected to the training pinions through a mechanical system of gearing and shafting. To compensate for misalignment of the B-end shaft and the final drive gearing, they are connected by flexible or self-aligning type couplings.

Auxiliary Pump Cluster

The auxiliary reduction gears are flange-mounted at the rear of the electric power motor. Three important pumps are driven by the motor through these gears. (See fig. 13-1.)

REPLENISHING PUMP.—This pump is a spur gear pump, driven at a constant speed by the electric motor through the auxiliary reduction gears. Its purpose is to replenish fluid to the active system of the power drive.

The pump draws fluid from the reservoir and discharges it at regulated pressure to the B-end valve plate. The discharge of the pump is held at a constant pressure (normally between 25 and 50 psi) by the action of a pressure relief valve. Normally, because the capacity of the pump exceeds replenishing demands, the relief valve is continuously dumping some of the fluid to return.

SUMP PUMP AND OSCILLATOR.—This pump is also driven by the electric motor through the auxiliary reduction gears. Its purpose is twofold. It pumps leakage, which collects in the sump of the indicator regulator, to the expansion tank.

Its other function is to transmit a pulsating effect to the fluid in the response pressure system. Oscillations in the hydraulic response system help eliminate static friction of valves to cause the hydraulic control to respond faster.

CONTROL PRESSURE PUMP.—The remaining pump driven through the auxiliary reduction gears is the control pressure pump. Its function is to supply high-pressure fluid for the hydraulic control system, brake pistons, lock piston, and the hand-controlled clutch operating piston.

The control pressure pump is an axial piston pump. It is similar to the A-end pump except that the angle of tilt is permanently fixed. Consequently, the pump produces a constant volume output.

To limit the pressure of the pump output to operating pressures, an adjustable relief valve, identical with that of the replenishing pump relief valve, is used. Fluid pressure can be measured by inserting a gage in the plughole located in the relief valve block.

RESERVOIR

The reservoir is used to hold the reserve fluid of the system. It also provides a large cooling surface for the fluid. The reservoir is a bronze tank of considerable surface area which is mounted on shock-absorbing pads on top of the reduction gear housing. External piping connects the reservoir to the hydraulic transmission, control devices, and the expansion tank.

EXPANSION TANK

The expansion tank (not shown in fig. 13-1), as the name indicates, provides space to allow for expansion of the volume of fluid in the hydraulic system due to changes in temperature. The expansion tank is mounted at the highest point in the hydraulic system and has a gage window in its side indicating the safe fluid level for operation of the equipment. A removable cap on the top of the tank serves as a fluid entry point for introducing fluid into the hydraulic system. A removable strainer is located at the fluid entry point to minimize the possiblity of particles of foreign matter entering the hydraulic system.

Since the expansion tank is at the highest point in the hydraulic system, the fluid in this tank serves to provide a positive pressure throughout the system and to prevent the entry of air into the transmission and valve blocks.

CONTROL

Control, as it pertains to the indicator regulator and the handwheel, is beyond the scope of this course. For the purposes of this course, control constitutes the relationship between the stroke control shaft and the tilting box. The

13097

stroke control shaft is physically located in the main cylinder. (See fig. 13-2.) It is the link between the hydraulic followup system and the power drive itself.

In hand control, the tilting box is mechanically positioned by gearing from the handwheel through the A-end control unit. In local and automatic control, the tilting box is positioned by the stroke control shaft. This shaft is connected at one end of the tilting box. On the other end, operating in the main cylinder, is the main piston. Intermediate high pressure (IHP) is transmitted to one side of the piston. The other side of the main piston is connected to high pressure (HPC), which is held constant at 1,000 psi. Since the area upon which HPC acts is exactly one-half the area upon which IHP acts, the main piston is held fixed in one position when IHP is one-half of HPC. Whenever IHP varies from normal value of one-half HPC, because of action of various control valves, the main piston will move, and thus cause movement of the tilting box.

BRAKE VALVES

An assembly consisting of two brake valves (pistons) acts to force the tilting box to its zero position whenever control pressure is released. (See fig. 13-3.) These spring loaded pistons are normally held back against the spring tension to allow the tilting box free movement. This is done by fluid pumped at high pressure from the control pressure pump. When fluid pressure drops, the pistons are moved by their springs to center the tilting box.

Figure 13-3.—Brake valves.

Figure 13-2.—Main cylinder assembly.

OPERATION

Figure 13-4 is a simplified block diagram showing the main elements of the hydraulic power drive system under automatic control for clockwise and counterclockwise rotation.

There are two principal problems in positioning a gun for fire. One is to get an accurate gun-order signal. This problem is solved by the gun director-computer combination. The other problem is to transmit the director signal promptly to the gun, and in such a manner that the position and movements of the gun will be synchronized with signals from the director. This problem is complicated by the fact that movements of the gun tend to fall behind or to overrun director signals, due in part to the lag inherent in transmitting the signals, but mainly

Figure 13-4.—Operation of the hydraulic power drive.

to the inertia of the gun. This inertia tends to keep the gun in movement if it is moving, and at rest if it is at rest, whereas the gun-order signal depends primarily on changes in the location of the target. These signals are always changing, not only because of changes in the relative position of the target and the ship, but also because of the roll and pitch of the ship.

The problem of transforming gun-order signals to mount movements is solved by the power drive and its control, the indicator regulator. The indicator regulator controls the power drive, and this in turn controls the movement of the gun.

The indicator regulator receives an initial electrical gun-order from the director-computer, compares it to the existing mount position, and sends an error signal to the hydraulic control mechanism in the regulator. The hydraulic control mechanism controls the flow to the stroke control shaft which positions the tilting box in the A-end of the transmission. Its tilt controls the volume and direction of fluid pumped to the B-end, and therefore the speed and direction of the drive shaft of the B-end. Through mechanical linkage the B-end output shaft moves the gun by an amount and in a direction determined by the signal.

At the same time, B-end response is transmitted to the indicator regulator, and continuously combines with incoming gun-order signals to give the error between the two. This error is modified hydraulically, according to the rate at which the error is changing, by a system of mechanical linkages and valves in the regulator. When the gun is lagging behind the signal, its movement is accelerated by this means, and, when it begins to catch up, its movement is slowed down so that it will not overrun excessively.

ELECTROHYDRAULIC STEERING

Electrohydraulic transmissions, similar to the one previously described, are utilized in many applications in the Navy. The pump-motor combinations may be either of the radial or axial piston type, and, as previously stated, are used to operate such equipment as capstans and winches aboard ship.

Most steering gear installations on modern naval ships are of the electrohydraulic type, but use only the A-end of the previously described hydraulic power drive. As the steering gear requires reciprocating motion, the B-end is replaced by a ram type actuating cylinder. The

13099

development of the electrohydraulic type of steering gear was prompted by the large momentary electrical power requirements for electromechanical steering—particularly for ships of large displacement and high speed. Also the elimination of direct current power from ships made switching and speed control of electric motors more difficult.

Advantages of the electrohydraulic steering gear are:

1. Little friction and inertia of moving parts, such as in heavy differential screws and gears.

2. Lower power consumption.

3. Sensitive response, with little lag, to movement of the steering wheel.

4. Small deck space and headroom required.

5. Saving in weight.

6. Flexibility in the arrangement of hydraulic cylinders, pumps, and control mechanisms.

7. Dependability.

TYPES

There are various types of electrohydraulic gear arrangements in use, but their operating principles are similar. Some ships have double hydraulic rams and cylinders (two dual ram assemblies) mounted fore and aft; others have double cylinder single ram (one dual ram assembly) mounted athwartship. Some systems use axial piston, variable displacement pumps; others use radial piston pumps.

Double Ram

Figure 13-5 shows a simple diagram of a double ram type electrohydraulic steering gear. Here, the rudder yoke is connected to two hydraulic plungers or rams. Each ram is equipped with cylinders at both ends. The pressure of the hydraulic fluid in the system is maintained by one of the two piston type, variable displacement pumps. The rate of fluid delivery is regulated by the angle of the tilting

Figure 13-5.—Double ram electrohydraulic steering gear.

13100

box in the hydraulic pump, which is controlled electrically or hydraulically from the steering wheel on deck. The control shaft and gear are indicated in figure 13-5.

Note that the after cylinder of the port ram is connected to the forward cylinder of the starboard ram and that the after cylinder of the starboard ram is connected to the forward cylinder of the port ram. A double-acting pressure relief valve serves to pass fluid from one working line to the other, thus relieving the piping from excessive strain, should unusual resistance to the rudder result in abnormal pressures.

Starting with a neutral position of the tilting box and no fluid flow, assume that the steering wheel is turned to starboard. Turning the wheel on the bridge causes an electric signal to be transmitted to the synchronous receiver in the steering gear room. (The synchronous receiver is part of the electrical steering gear control and is described later in this chapter.) The synchronous receiver will then turn correspondingly (counterclockwise in fig. 13-5 as viewed from the left). Shaft (A) is turned clockwise, carrying gear (B) with it. The gears (C), meshing with gear (B) and the internal gear teeth on (E), turn counterclockwise. Then (E) turns counterclockwise and turns the control shaft, which operates the tilting boxes on the pumps. A quantity of fluid now flows to the forward port and after starboard cylinders. The rudder is thereby caused to move to the right.

When the steering wheel and the synchronous receiver stop moving, the starboard ram, in moving forward, operates the rack and pinion and turns gear (D) clockwise. Gear (B) and shaft (A) are held by the now motionless receiver. Gear (C) and casing (E) turn clockwise, thus returning the tilting boxes to the neutral position and stopping the flow of fluid. The planetary differential gear, thereby operates as a followup mechanism. When the steering wheel is turned to port, the actions described are in the opposite direction.

In actual installations, two sets of synchronous receivers and two sets of electric motors and hydraulic pumps are provided for reliability and flexibility. The six-way plug valve makes it possible to transfer quickly from the operating pump to the standby pump.

Single Ram

The single ram type electrohydraulic steering gear, illustrated in figure 13-6, operates on the same principle as the double ram type. There is but one ram, with port and starboard cylinders, mounted athwartship. When the steering wheel is turned to starboard, fluid is directed to the port cylinder, forcing the ram to move to the right. The displaced fluid in the starboard cylinder returns to the pump. This movement of the ram causes the rudder to move to starboard.

CONTROL OF STEERING GEARS

Control of the steering gear from the steering wheel on the bridge may be accomplished by any of the following remote control systems:

1. Electrically, by means of an alternating-current synchronous transmission system.
2. Hydraulically, by means of a telemotor system.
3. Electrically, by means of a direct-current pilot motor and its controller.
4. Mechanically, by means of shafting or wire rope from the steering station.

The first two systems are most commonly used and therefore are described in the following paragraphs.

Alternating-Current Synchronous Transmission

The alternating-current synchronous transmission type of remote control consists of receiving and transmitting units which are similar to small motors. These units are connected to the same alternating-current supply. When the transmitter motor is turned, the receiver motor turns at the same speed and in the same direction.

The transmitters are located in steering stands at remote control stations and are mechanically connected through gearing to the steering wheels. A transmitter at each of the remote stations is electrically connected to a receiver in the steering room. The receiver is connected to the control shaft of the variable displacement hydraulic pump through a differential. Where more than one remote steering station is provided, a switch is provided on the steering stands and at the selector switch to indicate the selected circuit and that power is available.

Hydraulic Telemotor Control

The hydraulic telemotor type of remote control (fig. 13-7) is found on many Navy auxiliary

13101

Figure 13-6.—Single ram electrohydraulic steering gear.

ships that are equipped with electrohydraulic steering gear. The control system consists of a steering console (hydraulic transmitter) in the pilot house, a hydraulic receiver in the steering gear compartment, and connecting hydraulic tubing. In addition, there is an electric cable which connects the helm angle transmitter on the receiver housing with the helm angle indicator on the steering console.

A hydraulic transmitter is located inside the steering console and under the steering wheel. The hydraulic transmitter components consist of a pump, hydraulic tubing, two relief valves, two check valves, a replenishing tank, and a bypass valve. The remotely located receiver is a hydraulic ram type unit with two cylinders—one on each end of the receiver housing—in axial alignment. A double acting plunger (ram) operates in the cylinders. On the middle portion of this plunger a crosshead is connected for mechanical linkage to the steering gear control mechanism.

The direction of the hydraulic fluid movement depends upon the direction of rotation of the steering wheel. Rotating the steering wheel actuates bevel and spur gears which in turn operate a fixed displacement axial hydraulic pump. When the pump shaft and cylinder barrel are rotated by means of the steering wheel, the pistons draw fluid in from one fluid line and discharge it to the other fluid line. Reversing the rotation of the steering wheel reverses the direction of fluid flow through the pump. The pump has external check valves and piping for replenishing the hydraulic system from the reservoir. Relief valves and a bypass valve are also included, as well as vents for purging air from the system.

13102

When the hydraulic pump shaft is rotated in one direction, the fluid output is discharged from one side of the pump to one side of the receiver cylinder. In the other cylinder, hydraulic fluid is displaced to the pump. Thus, the hydraulic fluid under pressure moves the receiver plunger and produces a linear movement of the crosshead. This motion, in turn, is transmitted to the connected steering gear control mechanism. Travel of the crosshead and plunger is limited by adjustable stops on the receiver housing. In figure 13-7 (C), the solid arrows show direction of action for right rudder, while the broken arrows show the flow of hydraulic fluid for right rudder.

Air valves and filling or charging connections are provided on the receiver cylinders for venting, filling, or purging the hydraulic system. Specific filling and purging instructions for telemotor systems should be obtained from applicable steering gear or telemotor manuals, as these instructions vary, depending upon the type of unit and the specific installations. Care should be exercised, however, to insure that the replenishing tank for all types of systems be kept at least three-quarters full at all times.

MISSILE FLUID POWER SYSTEMS

All missiles must contain auxiliary power supply (APS) systems in addition to the main engine required for thrust. The APS systems

SOUTHWESTERN COTTON RUST

Cause

Southwestern cotton rust, Puccinia stakmanii, has been known in Arizona since 1922. Relatively mild in most years, it has caused considerable damage in certain years. Severe attacks occurred in Cochise County in 1959 and 1960. During these years yields were reduced one-quarter to one-half bale per acre on many farms as a result of leaf shed and boll damage. Serious outbreaks have also occurred in Pima and Santa Cruz Counties.

Look for rusted grama grass

The cotton rust fungus overwinters on grama grass (Fig. 1) and when favorable conditions are present, spores are produced which can be carried in the air to cotton. Severity of rust on cotton is related to the nearness and amount of rusted grama grass around cotton fields. Since there are thousands of spores on each rusted grass stem, heavy stands of infected grama may not be needed if weather conditions are favorable.

Fig. 1. Overwintering spores are found on grama grass.

Rust on cotton follows rain

Rainfall, followed by a period of high humidity, is needed to spread the fungus from grama grass to cotton. The first light showers, which may occur late in June or early July, are not effective in spreading the rust, but do prepare the spores for germination. Normally a rainfall of 1/2 inch or more followed by 12 - 18 hours of high humidity is needed for any sizeable amount of rust to develop.

Small yellow spots about the size of a pinhead will begin to appear on the upper surface of cotton leaves about one week after a large rainfall. These spots enlarge and soon yellow spores begin to appear on the bottom of the leaf (Fig. 2). The boll may also be infected (Fig. 3).

Fig. 2. Yellow spore masses on bottom of leaves.

Control of rust

Zineb is very effective in controlling Southwestern cotton rust, but it must be applied before the cotton becomes infected with the rust. This means that the spray schedule must start before the rains begin in July. The first spray should be applied in early July. Two additional sprays should be applied at 12 to 15 day intervals.

provide a source of power for the many devices required for successful missile flight. Some of the APS systems rely on the main combustion chamber as the initial source of power. Others have their own energy sources completely separate from the main propulsion unit. Whatever the initial source of energy, APS systems may be broken down in two broad categories—static and dynamic. In the static systems, energy is used in the same form in which it is stored. In the dynamic systems, energy is changed from one form to another by a conversion unit.

There are several general requirements for an APS system. First, the system must be able to deliver the necessary power during all conditions of missile flight. Second, the system must be able to respond quickly and accurately to demands made on it. Third, the system must be of minimum size and weight consistent with the requirements it must meet. Fourth, the system must be durable enough to withstand long storage under severe conditions.

BASIC SYSTEMS

As previously mentioned, the static APS systems use energy in the same form in which it is stored. Compressed air may be used directly to operate control system components. Static systems require no rotating machinery for energy conversion.

In dynamic systems, energy is changed from one form to another. For example, the potential energy of compressed air may be changed to electrical energy through an air-driven turbine and electric generator. Air motors or air turbines may be used to drive hydraulic energy transfer units. Figure 13-8 shows a basic pneumatic APS system. The air is led from the air flask through a pressure reducer and then to the air motor or air turbine.

Hydraulic fluid is also used extensively in guided missiles to transfer energy. An example is shown in figure 13-9. Compressed air or hot gas is used to exert pressure against a piston, and hydraulic fluid is then used to operate loads such as the control surfaces.

Figure 13-8.—Basic pneumatic system.

Figure 13-9.—Air or hot gases working against hydraulic piston.

The hydraulic fluid contains no energy in itself, but merely provides a means of transferring energy within a mechanism. Since, for all practical purposes, hydraulic fluid is noncompressible, it can be used to transfer energy with negligible losses. In addition to the air or hot gas method previously mentioned, axial and radial piston pumps, driven by turbines, are commonly used in guided missiles.

MISSILE CONTROL

A missile guidance system keeps the missile on the proper flightpath from launcher to target, in accordance with signals received from control points, from the target, or from other sources of information. The missile control system keeps the missile in the proper flight attitude.

Like an aircraft, whenever a missile changes its attitude in flight, it must turn about one or more of three axes. These axes are imaginary lines passing through the missile. The axes of a missile can be considered as imaginary axles around which the missile turns like a wheel. At the center, where all three axes intersect, each is perpendicular to the other two. The axis which extends lengthwise through the missile from the nose to the tail is called the longitudinal axis. The axis which extends crosswise, from one side to the other is called the lateral axis. The axis which passes through the center, from top to bottom is called the vertical axis.

Motion about the longitudinal axis resembles the roll of a ship from side to side. In fact, the names used in describing the motion about

13105

the three axes of a missile were originally nautical terms. They have been adapted to aeronautical terminology because of the similarity of motion between an aircraft or missile, and a ship.

Thus, the motion about the longitudinal axis is called roll. Likewise, motion along the lateral (crosswise) axis is called pitch. This is similar to the pitching motion of an ocean vessel as it plows in heavy seas. Finally, a missile moves about its vertical axis in a motion which is termed yaw.

The missile control system keeps the missile in the proper flight attitude by controlling the movements—roll, pitch, and yaw—around the corresponding axes—longitudinal, lateral, and vertical.

Methods of Control

Some missiles are controlled by control surfaces similar to aircraft. The ailerons control roll about the longitudinal axis; the elevator controls pitch around the lateral axis; and the rudder controls yaw about the vertical axis. Jet vanes, movable jets, and fixed steering jets, are also commonly used for control of missiles. The control surface method is presented here because it illustrates the basic principles of control functions.

Types of Control Systems

Regardless of which method is used in controlling the attitude of the missile in flight, the latent power is drawn from one of the auxiliary power systems previously described. The power is transmitted from the supply sources to the movable controls by pneumatic means, by electrical means, by mechanical means, or by using a hydraulic transfer system in conjunction with the other sources. Pneumatic and hydraulic systems are described in the following paragraphs.

PNEUMATIC.—In a pneumatic system, air from a pressurized source passes through lines, valves, and pressure regulators to the transfer (directional control) valve where it is directed to the actuator. The pressurized source generally consists of high pressure air, or nitrogen stored in flasks or bottles.

The pneumatic system does not re-use its transfer medium after it has performed work. For that reason, the air must be stored at a pressure much higher than that necessary for actuating the load in order to maintain adequate system pressure as the stored air supply diminishes.

Figure 13-10 illustrates two double-acting piston type pneumatic actuators used for rudder and elevator control. The air transfer valve is mechanically linked to an air relay (not shown) which receives the air error signal produced by deviations in yaw of the missile. The relay action is such that both force and sense of the error signal are transmitted to the air valve. Thus, the initial direction of displacement of the air transfer valve is determined by the sense of the error signal. Assume that a yaw deviation has occurred, and that the error signal from the air relay has caused the air transfer valve to move toward the right, thus opening the right port of the actuating cylinder. Air from the high-pressure inlet passes through this port and causes the actuator piston rod to move toward the left. Simultaneously, air is forced from the left-hand section of the actuator cylinder through the port located in that section. This displaced air is exhausted into the atmosphere through the air transfer valve exhaust port located at the left end of the air transfer valve.

The actuator piston motion is transmitted through the mechanical linkage to the rudder, which applies corrective control in the proper direction to bring the missile back to the desired yaw position. As the piston moves, it exerts a force on the followup spring. The followup spring is a calibrated coil spring connected between the piston rod and the air transfer valve. Movement of the piston puts the spring in a state of tension or compression, depending upon the direction of piston displacement. In either state, the followup spring exerts a force on the air transfer valve which opposes the force exerted by the air relay. Thus, the air transfer valve movement is the difference of two forces and is in the direction of the resultant force. Movement of the actuator piston continues until the force exerted by the followup spring is equal, but opposite in direction, to the force exerted on the air transfer valve by the air relay. When this condition is established, the air transfer valve spool is centered, and actuator piston movement stops. With the air transfer valve thus balanced, air leaks past the air transfer valve spool and puts equal pressure on both sides of the actuator piston. This action holds the piston, and the rudder to which it is linked, in

Figure 13-10.—Pneumatic control system.

the corrective position ordered by the air error signal.

The force applied to the rudder causes the missile to turn toward the desired flight attitude. Since the missile is now moving in a direction which is opposite to that during off course displacement, an opposing air rate signal is applied to the air relay. This air signal reduces the force that the air relay is exerting against the air transfer valve. As the missile approaches normal attitude in yaw, the force exerted by the followup spring is greater than that exerted by the air relay. Now the air transfer valve moves to the left and air from the high-pressure inlet forces the actuator piston toward its neutral position; that is, the direction of motion of the piston is now from left to right. This action results in partial removal of the control force applied to the rudder. As the amount of control is reduced, the force exerted by the followup spring is reduced. Therefore, the rate of turn and consequently the rate signal are also reduced. Thus, all forces are continually being reduced as the missile approaches normal attitude. When normal attitude is regained, the air signal is zero, the followup spring force is zero, and the actuator piston and rudder are again centered. All movement ceases until the missile again deviates in yaw due to air gusts or its own flight characteristics.

The elevator control actuator, shown in figure 13-10, operates exactly the same as the rudder except for the manner in which the mechanical linkage is connected to the elevator. The elevator provides pitch control. A similar arrangement is used to operate ailerons for roll control.

PNEUMATIC-ELECTRIC.—The pneumatic control system just described can be combined with other systems to refine the control action. Electric signal pickoffs are accurate and dependable. They can provide a signal voltage that is proportional to displacement. They have a decided advantage over pneumatic systems in transporting information over wires, instead of through tubing.

It is difficult to design a small electric motor with sufficient speed and power to actuate

13107

missile flight control surfaces. Figure 13-11 illustrates a control system in which the best features of electric and pneumatic systems are used. Electrical equipment is used in the front end and actuates pneumatic servos at the actuating end.

Pneumatic controls are comparatively slow because air is compressible, and time is required to build up enough pressure in a cylinder to move the piston. Since the piston is linked mechanically to the flight control surfaces, there is a time lag between the control signal and the movement of the control surface. But the slow response can be speeded up by adding a booster cylinder, as shown in figure 13-11.

The increase in response speed is obtained by allowing air to escape, through ports, into a relief valve after the servo valve has moved a certain distance from midposition. The relief valve lets high-pressure air into the boost cylinder, which then acts in parallel with the actuator cylinder to move the flight control surfaces. The additional force provided by the boost cylinder makes it possible to obtain large control surface deflections in either direction.

The sensors for a pneumatic-electric system are electric pickoffs that detect gyro displacement and produce a voltage proportional to the heading deviation angle. This voltage is small and must be amplified before it can operate a solenoid and air servo valve.

The change from electric to pneumatic operation takes place at the air servo valve. The air servo motor rotates the torque tubes which are connected to the control surfaces and extend into the center section of the missile. This system may be used for either pitch or yaw control.

The servoamplifier receives a followup signal from the control surface through mechanical linkage and electrical voltage. The feedback voltage cancels the input voltage when the control surfaces have deflected a certain amount. The deflection of the control surfaces is therefore proportional to the input signal.

HYDRAULIC-ELECTRIC.—This combination is similar to the pneumatic-electric, except that the actuators are moved by hydraulic fluid pressure instead of air pressure. This removes some of the disadvantages of a pneumatic system, since the fluid is not compressible. The hydraulic-electric method of control

Figure 13-11.—Pneumatic-electric control system.

COPY 13108

is used more than any other types of system. The most important advantages of this type system are the high speed of response and the large forces available when using hydraulic actuators.

Figure 13-12 illustrates a simplified block diagram of a hydraulic-electric controller. This system is composed of the following components:

1. A reservoir, which contains the supply of hydraulic fluid.
2. A motor, as a source of power for the pump. It may be either an electric or air motor.

Figure 13-12.—Basic hydraulic controller.

3. A pump, to move the fluid through the system.
4. A relief valve, to prevent excessive pressure in the system.
5. An accumulator, which acts as an auxiliary storage space for fluid under pressure, and as a dampening mechanism which smoothes out pressure surges within the system.
6. A transfer (directional control) valve, which controls the flow of fluid to the actuator. In some systems of this type a servo valve is used instead of a transfer valve. The servo valve provides finer control.

Variations in pitch, roll, and yaw are sensed by gyro reference units with electrical pickoffs. The pickoff voltages are fed to amplifiers and computers and are then used to operate a controller. The controller, a hydraulic transfer or servo valve regulates the amount and direction of flow to the actuator.

Figure 13-13 shows a hydraulic-electric system for roll control. The system uses proportional control only, which means that the controls react to information that shows the deviation of the missile axis from the desired flightpath. The displacement signal is proportional to the deviation.

Should roll develop, the gyro will detect it and cause the synchro to produce an error signal. The correction signal to the servoamplifier is

Figure 13-13.—Hydraulic-electric system for roll control.

OFFICI 13109

the difference between the followup signal and the gyro signal, as indicated by the minus sign in the circle between the synchro block and the servoamplifier triangle.

The difference signal is amplified and used to operate the transfer valve and regulates the flow of fluid to the actuator. This piston in this actuator operates the ailerons (or other roll devices) through mechanical linkage.

The equipment represented by the block labeled "jitter" provides an a-c voltage with a frequency of about 25 cycles per second. This is applied to the transfer valve and other equipment, to keep them in constant vibration and prevent the friction that may develop when the parts are not moving.

AIRCRAFT FLUID POWER SYSTEMS

All modern naval aircraft contain hydraulic systems for the operation of various mechanisms. The number of hydraulically operated units depends upon the model of aircraft. At the present time, the average operational aircraft has a dozen or more hydraulically operated units. Many aircraft are equipped with pneumatic systems for the operation of certain mechanisms. The pneumatic system is also utilized as an emergency system in case of hydraulic system failure.

A complete aircraft hydraulic or pneumatic system consists of a power system and any number of actuating systems (subsystems), the number of actuating systems depending upon the design of the aircraft.

The power system is generally considered to include the fluid supply (reservoir or air bottles), power supply (pump or compressor), and all other components leading up to, but not including, the selector (directional control) valves. The selector valves direct the flow of fluid to the various actuating units, and each selector valve is considered a part of its related actuating system.

The hydraulic and pneumatic systems of a modern fighter aircraft are described in this section. Only the power systems are described in detail. Most of the actuating systems, which are indicated in the illustrations, are controlled by solenoid operated four-way selector valves. The actuators are piston type actuating cylinders or, in some subsystems, fluid motors.

HYDRAULIC SYSTEMS

Current aircraft hydraulic system specifications require two separate systems for operating the flight controls. All aircraft which utilize hydraulically actuated flight controls have at least two hydraulic power systems, one of which supplies fluid pressure to the utility or normal system in addition to the flight controls. The utility system operates the landing gear, wing fold, wheel brakes, and other such units. Most manufacturers refer to the systems supplying pressure only for the flight control surfaces as the power control systems. If there are three hydraulic power systems, they are generally referred to as power control system 1 (PC-1), power control system 2 (PC-2), and utility system. Each system has its own reservoir, power pump, and lines.

Power systems are designed to produce and maintain a given pressure. The pressure output of the Navy's high performance aircraft is 3,000 psi. However, some aircraft hydraulic systems operate at only 1,500 psi.

Figure 13-14 illustrates a utility hydraulic system. This particular aircraft has two other independent hydraulic systems for the operation of the flight controls. All three systems operate at 3,000 psi. A description of the utility power system components and their functions follows.

Reservoir

The reservoir is the source from which the hydraulic pumps draw their supply of fluid, and a storage container for the return fluid displaced by the actuating components. The reservoir is liquid-pressurized. This insures a supply of fluid to the pumps at all times.

Pumps

The flow of fluid to the system is provided by two variable displacement axial piston pumps, one mounted on each engine. Each pump has an integral compensator that regulates volume delivery in accordance with system flow demands. The flow from the pump is ported to a manifold line from which branch lines lead off to the various actuating systems.

Check Valves

Check valves near the pump pressure ports prevent any backfeed of system pressure against

13110

Figure 13-14.—Aircraft hydraulic system.

13111

NATIONAL BUREAU OF STANDARDS-1963-A

the pump output and prevent pressure supplied from an external hydraulic power source from attempting to motor the pump (rotating it in reverse), possibly shearing or damaging the pump-to-engine drive spline. Check valves are installed in the system return lines to direct return flow back to the reservoir and to prevent pressure from acting against the return ports of other system components. A check valve is incorporated in the line to the brake system. In normal operating conditions, the check valve allows free flow from the system to the brake system. When system pressure drops below 1,500 psi, the check valve is forced closed from the 1,500 psi accumulator pressure. This maintains a limited amount of fluid under pressure for brake operation during peak demands of the utility system or in the event of system failure.

Accumulators

An accumulator is installed in the manifold line to dampen pump pulsations, which maintains smoothness of system operation. In addition, this accumulator assists the pumps by providing the system with a limited amount of fluid and pressure during peak system power demands. (The function of the accumulator in the brake system was described under check valves.)

Accumulator servicing is accomplished via the connecting air charge valve. The attached pressure gage is used to check the accumulator air charge and to determine the degree of system pressurization.

Filters

Filters are installed in both the system pressure and return lines. The filter elements are of the micronic type. A filter bypass valve allows fluid to flow through the top of the filter instead of the filter element should the element become clogged. Filters are also installed in various actuating systems.

Relief Valve

A system relief valve is installed in the system to protect it from detrimental pressure surges and to limit system pressure buildup in excess of 3,850 psi, by dumping the fluid to return.

Pressure Switches

There are two pressure switches installed in the utility system. They are installed in the pressure lines leading from the pumps and are isolated from one another by the check valves. When the pressure from one or the other pump drops below 1,500 psi the pressure switch completes an electrical circuit that illuminates a warning light in the cockpit.

Heat Exchanger

The heat exchangers are honeycomb radiators, similar to an automobile radiator, located in the fuel tanks. The hydraulic fluid returning to the reservoir is routed through the heat exchangers. The heat energy is transferred from the hydraulic fluid to the cooler fuel.

The utility power system provides fluid under pressure for those actuating systems indicated in figure 13-14. The number of actuating systems vary in different types of aircraft. The PC-1 and PC-2 systems are similar to the utility system and provide fluid under pressure for the operation of the flight control systems.

PNEUMATIC SYSTEMS

The pneumatic power system supplies compressed air for various normal and emergency pneumatic actuating systems. The compressed air is stored in storage bottles in the actuating systems until required by actuation of the system. These bottles and the power system manifold lines are initially charged with compressed air or nitrogen from an external source through a single air charge valve. In flight, the air compressor replaces the air pressure and volume lost through leakage, thermal contraction, and system operation.

The pneumatic system provides power for the normal operation of the cockpit enclosures and emergency operation of such components as landing gear extension and the brake system. The number of normal and emergency systems operated by the pneumatic systems vary in different model aircraft.

The emergency operation is controlled by a three-way spool type selector valve. Usually, the valve is manually operated from the cockpit through mechanical linkage. The compressed air flows into the shuttle valve which is in the working line of the hydraulic system. The air pressure forces the shuttle valve to close the hydraulic inlet port. The air then flows to the actuator.

11161 13112

189

The air compressor is supplied with supercharged air from the engine air system. This insures an adequate supply of air to the compressor at all altitudes.

The air compressor may be driven by an electric motor or a hydraulic motor. The system described in this section is hydraulically driven. (See fig. 13-15.)

Power Supply

The aircraft utility hydraulic system provides power to operate the hydraulic motor driven compressor. The air compressor hydraulic actuating system consists of a solenoid-operated selector valve, flow regulator, hydraulic motor, and check valve. When energized,

Figure 13-15.—Pneumatic power system.

13113

Zineb may be obtained in three different forms; less plugging of spray nozzles occurs when the wettable powder form (Dithane Z-78) is used. If the wettable powder is used, two pounds of the material plus a suitable sticker spreader in 40 gallons of water should be applied per acre.

Compatibility charts indicate zineb may be mixed with most insecticides; however, this should be checked with your insecticide salesman. If insecticides are mixed with zineb, they should be added to the tank mixture last.

Application should be made with a ground sprayer having three to five nozzles per row for thorough coverage. Side nozzles should be placed at 45° forward in line of travel and angled up or down depending on location.

Fig. 3.

None of the fungicides tested thus far will eradicate the fungus or alter its normal development once the fungus is established in the tissues of the cotton plant. Therefore, for successful control of cotton rust it is necessary to have the protecting fungicide on the plant before the infective spores come in contact with the cotton plant.

flames or hot particles, which could result in an explosion, and to relieve excessive pressure buildups.

The flame arrester, a cylindrical shaped fine mesh steel screen, is placed immediately inside of the safety fitting inlet port. Its purpose is to prevent the passage of flame or hot carbon particles, emanating from a buildup of carbon deposits in the air compressor. The stainless steel rupture disc is designed to burst and relieve excessive pressures (4,750 psi), to prevent a shrapnel-like explosion of the moisture separator.

Chemical Drier

A chemical drier further reduces the moisture content of the air emerging from the moisture separator.

Air Charge Valve

The air charge valve provides the entire pneumatic system with a single external servicing point. An air pressure gage, located near the air charge valve, is used in servicing the system. This gage indicates the system pressure.

13115

APPENDIX I

GLOSSARY

ABSOLUTE PRESSURE.—Actual pressure (includes atmospheric pressure).

ABSOLUTE TEMPERATURE.—The temperature measured using absolute zero as a reference. Absolute zero is -273.16° C or -459.69° F.

ACCELERATION.—Time rate of change of velocity.

ACCUMULATOR.—A device for storing liquid under pressure, usually consisting of a chamber separated into a gas compartment and a liquid compartment by a piston or diaphragm. An accumulator also serves to smooth out pressure surges in a hydraulic system.

ACTUATING CYLINDER.—An actuator which converts fluid power into linear mechanical force and motion.

ACTUATOR.—A device which converts fluid power into mechanical force and motion.

ADDITIVE.—A chemical compound added to a fluid to change its properties.

AFTERCOOLER.—A device which cools a gas after it has been compressed.

AIR BLEEDER.—A device used to remove air from a hydraulic system. It may be a needle valve, capillary tubing to the reservoir, or a bleed plug.

AMBIENT.—Surrounding, such as ambient air meaning surrounding air.

ANEROID.—Containing no liquid, as an aneroid barometer.

BACK PRESSURE.—A pressure exerted contrary to the pressure producing the main flow.

BAROMETER.—An instrument which measures atmospheric pressure.

BERNOULLI'S PRINCIPLE.—If a fluid flowing through a tube reaches a constriction, or narrowing of the tube, the velocity of fluid flowing through the constriction increases and the pressure decreases.

BOYLE'S LAW.—The volume of any dry gas varies inversely with the applied pressure, provided the temperature remains constant.

BUOYANCY.—The upward or lifting force exerted on a body by a fluid.

CALIBRATE.—To make adjustments to a meter or other instrument so that it will indicate correctly with respect to its inputs.

CATALYST.—A substance used to speed up or slow down a chemical reaction, but is itself unchanged at the end of the reaction.

CENTIGRADE.—The temperature scale using the freezing point as zero and the boiling point as 100, with 100 equal divisions between, called degrees.

CENTRIFUGAL FORCE.—A force exerted on a rotating object in a direction outward from the center of rotation.

CHARLES' LAW.—If the pressure is constant, the volume of a dry gas varies directly with the absolute temperature.

CHECK VALVE.—A valve which permits fluid flow in one direction, but prevents flow in the reverse direction.

CHEMICAL CHANGE.—A change which alters the composition of the molecules of a substance. New substances with new properties are produced.

COMPRESSED AIR.—Considered as air at any pressure in excess of the local atmospheric pressure.

COMPRESSIBILITY.—The property of a substance, such as air, by virtue of which its density increases with increase in pressure.

COMPRESSOR.—A mechanical device used for increasing the pressure of a fluid; for example, an air compressor.

CONDENSATION.—The change from a gaseous (or vapor) state to a liquid state.

CONTAMINATION.—Harmful foreign matter in a fluid.

CONTROL.—A means or device used to regulate the function of a unit. For example, valves

13116

may be controlled hydraulically, manually, mechanically, electrically, or pneumatically. In turn, the valve controls the function of some unit.

CONVERGENT.—That which inclines and approaches nearer together, as the inner walls of a tube that is constricted.

CORROSION.—The slow destruction of materials by chemical agents and electromechanical reactions.

COUNTERBALANCE VALVE.—A valve which permits free flow in one direction, but maintains a resistance to flow in the other direction to prevent a load from falling

DENSITY.—The weight per unit volume of a substance.

DIAPHRAGM.—A dividing membrane or thin partition.

DIFFUSER.—A duct of varying cross section designed to convert a high-speed gas flow into low-speed flow at an increased pressure.

DIRECTIONAL CONTROL VALVE.—A valve which selectively directs or prevents flow to or from desired channels. Also referred to as selector valve, control valve, or transfer valve.

DISPLACEMENT.—The volume of fluid which can pass through a pump, motor, or cylinder in a single revolution or stroke.

DIVERGENT.—Moving away from each other, as the inner walls of a tube that flares outward.

DOUBLE-ACTING CYLINDER.—An actuating cylinder in which both strokes are produced by pressurized fluid.

DYNAMIC PRESSURE.—The pressure of a fluid resulting from its motion, equal to one-half the fluid density times the fluid velocity squared. In incompressible flow, dynamic pressure is the difference between total pressure and static pressure.

EFFICIENCY.—The ratio of output power to input power, generally expressed as a percentage.

ENERGY.—The ability or capacity to do work.

EQUILIBRIUM.—A state of balance between opposing forces or actions.

FAHRENHEIT.—The temperature scale using the freezing point as 32 and the boiling point as 212, with 180 equal divisions between, called degrees.

FEEDBACK.—A transfer of energy from the output of a device back to its input.

FIXED DISPLACEMENT.—The type of pump or motor in which the volume of fluid per cycle cannot be varied.

FLASH POINT.—The temperature at which a substance, such as a fluid, will give off a vapor that will flash or burn momentarily when ignited.

FLOW CONTROL VALVE.—A valve which is used to control the flow rate of fluid in a fluid power system.

FLOWMETER.—An instrument used to measure quantity or the flow rate of a fluid in motion.

FLUID.—Any liquid, gas, or mixture thereof.

FLUID FLOW.—The stream or movement of a fluid, or the rate of its movement.

FLUID POWER.—Power transmitted and controlled through the use of fluids, either liquids or gases, under pressure.

FOOT-POUND.—The amount of work accomplished when a force of 1 pound produces a displacement of 1 foot.

FORCE.—The action of one body on another tending to change the state of motion of the body acted upon. Force is usually expressed in pounds.

FREE FLOW.—Flow which encounters negligible resistance.

FRICTION.—The action of one body or substance rubbing against another, such as fluid flowing against the walls or a pipe; the resistance to motion caused by this rubbing.

FRICTION PRESSURE DROP.—The decrease in the pressure of a fluid flowing through a passage attributable to the friction between the fluid and the passage walls.

GAGE PRESSURE.—Pressure above atmospheric pressure.

GAGE SNUBBER.—A device installed in the line to the pressure gage used to dampen pressure surges and thus provide a steady reading and a protection for the gage.

GAS.—The form of matter which has neither a definite shape nor a definite volume.

GASKET.—A class of seal which provides a seal between two stationary parts.

GRAVITY.—The force which tends to draw all bodies toward the center of the earth. The weight of a body is the resultant of all gravitational forces acting on the body.

HEAD.—A measure of fluid pressure as the height of a fluid column necessary to cause that pressure at its base. The pressure of a fluid owing to its elevation.

HORSEPOWER.—A unit for measuring the power of motors or engines, equal to a rate of 33,000 foot-pounds per minute. The force required to raise 33,000 pounds at the rate of 1 foot per minute.

13117

HYDRAULICS.—That branch of mechanics or engineering that deals with the action or use of liquids forced through tubes and orifices under pressure to operate various mechanisms.

HYDROMETER.—An instrument for determining the specific gravities of liquids.

IMPACT PRESSURE.—That pressure of a moving fluid brought to rest which is in excess of the pressure the fluid has when it does not flow; that is, total pressure less static pressure. Impact pressure is equal to dynamic pressure in incompressible flow; but in compressible flow, impact pressure includes the pressure change owing to the compressibility effect.

IMPINGEMENT.—The striking or dashing upon with a clash or sharp collision, as air impinging upon the rotor of a turbine or motor.

IMPULSE TURBINE.—A turbine driven by a fluid at high velocity under relatively low pressure.

INERTIA.—The tendency of a body at rest to remain at rest, and a body in motion to continue to move at a constant speed along a straight line, unless the body is acted upon in either case by an unbalanced force.

INHIBITOR.—Any substance which retards or prevents such chemical reactions as corrosion or oxidation.

INTEGRAL.—Essential to completeness, as an integral part. (The valve stem is an integral part of the valve.)

INTERCOOLER.—A device which cools a gas between the compression stages of a multiple stage compressor.

INVERSE PROPORTION.—The relation that exists between two quantities when an increase in one of them produces a corresponding decrease in the other.

KELVIN SCALE.—The temperature scale using absolute zero as the zero point and divisions that are the same size as centigrade degrees.

KINETIC ENERGY.—The energy which a substance has while it is in motion.

KINETIC THEORY.—A theory of matter which assumes that the molecules of matter are in constant motion.

LAMINA.—A layer of fluid.

LAMINAR FLOW.—A smooth flow in which no cross flow of fluid particles occurs.

LINE.—A tube, pipe, or hose which is used as a conductor of fluid.

LIQUID.—A form of matter which has a definite volume but takes the shape of its container.

LOAD.—The power that is being delivered by any power-producing device. The equipment that uses the power from the power-producing device.

MATTER.—Any substance which occupies space and has weight. The three forms of matter are solids, liquids, and gases.

MECHANICAL ADVANTAGE.—The ratio of the resisting weight to the acting force. The ratio of the distance through which the force is exerted divided by the distance the weight is raised.

METER-IN.—To regulate the amount of fluid into a system or an actuator.

METER-OUT.—To regulate the flow of fluid from a system or actuator.

MICRON.—A millionth of a meter or about 0.00004 inch.

MOLECULE.—A small natural particle of matter composed of two or more atoms.

MOTOR.—An actuator which converts fluid power to rotary mechanical force and motion.

NEOPRENE.—A synthetic rubber highly resistant to oil, light, heat, and oxidation.

OSCILLATION.—A backward and forward motion, a vibration.

OXIDATION.—That process by which oxygen unites with some other substance, causing rust or corrosion.

PACKING.—A class of seal which is used to provide a seal between two parts or a unit which move in relation to each other.

PASCAL'S LAW.—Whenever an external pressure is applied to any confined fluid at rest, the pressure is increased at every point in the fluid by the amount of the external pressure.

PERIPHERY.—The outside surface, especially that of a rounded object or body.

PHYSICAL CHANGE.—A change which does not alter the composition of the molecules of a substance.

PILOT VALVE.—A valve used to control the operation of another valve.

PIPE.—That type of fluid line the dimensions of which are designated by nominal (approximate) outside diameter (OD) and wall thickness. (See also TUBING.)

PISTON TYPE CYLINDER.—An actuating cylinder in which the cross-sectional area of the piston rod is less than one-half the cross-sectional area of the movable element.

PLUNGER.—(See RAM TYPE CYLINDER.)

PNEUMATICS.—That branch of physics pertaining to the pressure and flow of gases.

13118

PORT.—An opening for the intake or exhaust of a fluid.

POTENTIAL ENERGY.—The energy a substance has because of its position, its condition, or its chemical composition.

POWER.—The rate of doing work or the rate of expanding energy.

PRESSURE.—The amount of force distributed over each unit of area. Pressure is expressed in pounds per square inch (psi).

PRESSURE DIFFERENTIAL.—The difference in pressure between any two points of a system or a component.

PRESSURE SWITCH.—An electrical switch operated by the increase and decrease of fluid pressure.

PRIME MOVER.—The source of mechanical power used to drive the pump or compressor.

PUMP.—A device which converts mechanical energy into fluid energy.

RAM TYPE CYLINDER.—An actuating cylinder in which the cross-sectional area of the piston rod is more than one-half the cross-sectional area of the movable element. Also referred to as plunger.

RANKINE SCALE.—A thermometer scale based on absolute zero of the Fahrenheit scale, in which the freezing point of water is approximately 492° R.

RATIO.—The value obtained by dividing one number by another, indicating their relative proportions.

RECEIVER.—A container in which gas is stored under pressure as a supply source for pneumatic power.

RECIPROCATING.—Moving back and forth, as a piston reciprocating in a cylinder.

RELIEF VALVE.—A pressure control valve used to limit system pressure.

RESERVOIR.—A container which serves primarily as a supply source of the liquid for a hydraulic system.

RESTRICTION.—A reduced cross-sectional area in a line or passage which reduces the rate of flow.

RETURN LINE.—A line used for returning fluid back into the reservoir or atmosphere.

SEQUENCE VALVE.—An automatic valve in a fluid power system that causes one actuation to follow another in definite order.

SERVO.—A device used to convert a small movement into a greater movement or force.

SERVOCONTROL.—A control actuated by a feedback system which compares the output with a reference signal and makes corrections to reduce the differences.

SHUTOFF VALVE.—A valve which operates fully open or fully closed.

SHUTTLE VALVE.—A valve which is used to direct fluid automatically from either the normal source or an alternate source to the actuator.

SINGLE-ACTING CYLINDER.—An actuating cylinder in which one stroke is produced by pressurized fluid, and the other stroke is produced by some other force, such as gravity or spring tension.

SOLID.—The form of matter which has a definite shape and a definite volume.

SPECIFIC GRAVITY.—The ratio of the weight of a given volume of a substance to the weight of an equal volume of some standard substance.

STABILITY.—The resistance of a fluid to permanent change in properties due to chemical reaction, temperature changes, etc.

STEADY FLOW.—A flow in which the velocity components at any point in the fluid do not vary with time.

STREAMLINE FLOW.—A smooth, nonturbulent flow, essentially fixed in pattern.

STUFFING BOX.—A chamber and closure with manual adjustment for a sealing device.

SUPPLY LINE.—A line that conveys fluid from the reservoir to the pump.

SURGE.—A momentary rise of pressure in a system.

SYNCHRONIZE.—To make two or more events or operations occur at the proper time with respect to each other.

SYNCHRONOUS.—Happening at the same time.

SYNTHETIC MATERIAL.—A complex chemical compound which is artificially formed by the combining of two or more simpler compounds or elements.

THEORY.—A scientific explanation, tested by observations and experiments.

THERMAL EXPANSION.—The increase in volume of a substance due to temperature change.

TORQUE.—A force or combination of forces that produces or tends to produce a twisting or rotary motion.

TUBING.—That type of fluid line the dimensions of which are designated by actual measured outside (OD) and by actual measured wall thickness.

TURBINE.—A rotary motor actuated by the reaction, impulse, or both, of a flow of

13119

pressurized fluid. A turbine usually consists of a series of curved vanes on a centrally rotating shaft.

TURBULENCE.—A state of flow in which the fluid particles move in a random manner.

VACUUM.—Pressure less than atmospheric pressure.

VARIABLE DISPLACEMENT.—The type of pump or motor in which the volume of fluid per cycle can be varied.

VELOCITY.—The rate of motion in a particular direction. The velocity of fluid flow is usually measured in feet per second.

VENTURI.—A tube having a narrowing throat or constriction to increase the velocity of fluid flowing through it. The flow through the venturi causes a pressure drop in the smallest section, the amount being a function of the velocity of flow.

VISCOSITY.—The internal resistance of a fluid which tends to prevent it from flowing.

VOLUME OF FLOW.—The quantity of fluid that passes a certain point in a unit of time. The volume of flow is usually expressed in gallons per minute for liquids and cubic feet per minute for gases.

WORK.—The transference of energy from one body or system to another. That which is accomplished by a force acting through a distance.

TEXAS ROOT ROT OF ALFALFA

Alfalfa is very susceptible to Texas root rot caused by the fungus Phymatotrichum omnivorum. Control of the disease in a perennial crop such as alfalfa is difficult.

Alfalfa, with a tap root penetrating many feet into the soil, is perhaps the best test plant for determining the presence or absence of the root rot fungus. A good, young stand of alfalfa will average several plants per square foot and these penetrate the soil mass so thoroughly that roots will come in contact with any root rot fungus present and infection will take place.

Symptoms

Alfalfa is normally seeded in October in Southern Arizona but usually no trace of root rot, even on heavily infested soil, is seen until the latter part of June of the next year when a few individual plants die suddenly. Adjacent plants soon die in a circular pattern and the circles become larger with each cutting (Fig. 1).

The root rot infection advances from 6 to 15 feet during the growing season. Individual spots are circular initially, but as they enlarge and intersect other spots, the pattern becomes irregular. If root rot is general in the field, the stand may be badly depleted in one year, although occasionally the stand survives for two or three years, but hay yield is

Fig. 1. Plants die in circular pattern. The dead areas enlarge from 6 to 15 feet during a growing season.

ABSTRACT - Prepared by the Navy Training Publications Center, this training manual is one in a series prepared for enlisted personnel of the Navy who are preparing for advancement to AT3 and AT2. Contents are: (1) Aviation Electronics Technician Rating, (2) Aircraft Maintenance, (3) Safety, (4) Publications, Drawings, and Schematics, (5) Elementary Physics, (6) Electric Power and Cooling Systems, (7) Handtools, (8) Electronic Test Equipment, (9) Electronic Principles, (10) Electronic Circuits, (11) Special Circuits and Components, (12) Servosystems, (13) Electronic Maintenance, (14) Digital Computers, (15) Communication Facilities, (16) Airborne Navigation Equipment, (17) Airborne Radar, (18) Principles of IFF, (19) Electronic Countermeasures, and (20) Infrared Detection. Formulas, Symbols, Greek Alphabet, and laws of exponents are appended. A related document is available as VT 008 298, also in this issue. (GB)

BUREAU OF NAVAL PERSONNEL

RATE TRAINING MANUAL NAVPERS 10317-D

PREFACE

This Rate Training Manual is one of a series of training manuals prepared especially for enlisted personnel of the U.S. Navy and Naval Reserve who are preparing for advancement to AT3 and AT2. Since all personnel seeking advancement to these levels are not held responsible for the entire contents of this training manual, a study guide is included.

The Manual of Qualifications for Advancement, NavPers 18068 (Series), has been used as a guide in the selection of content for this training manual. Trainees should become familiar with the qualifications for advancement prior to starting work on this manual.

Of the 21 chapters in this training manual, 20 are concerned with the technical aspects of the AT rating. Chapter 1 contains introductory information with which the trainee should familiarize himself before studying the other chapters.

Basic Electricity, NavPers 10086 (current edition), and Basic Electronics, NavPers 10087 (current edition), contain essential background information for the AT rating. Some U.S. Armed Forces Institute courses, the content of which are closely related to the AT rating, are listed in the Reading List.

This Rate Training Manual has been prepared by the Navy Training Publications Center, NAS Memphis, Millington, Tennessee, for the Bureau of Naval Personnel. Credit is given to the Naval Air Technical Training Center, located at NAS Memphis, Millington, Tennessee, the Naval Examining Center, Great Lakes, Illinois, and the Naval Air Systems Command for technical reviews.

THE UNITED STATES NAVY

GUARDIAN OF OUR COUNTRY

The United States Navy is responsible for maintaining control of the sea and is a ready force on watch at home and overseas, capable of strong action to preserve the peace or of instant offensive action to win in war.

It is upon the maintenance of this control that our country's glorious future depends; the United States Navy exists to make it so.

WE SERVE WITH HONOR

Tradition, valor, and victory are the Navy's heritage from the past. To these may be added dedication, discipline, and vigilance as the watchwords of the present and the future.

At home or on distant stations we serve with pride, confident in the respect of our country, our shipmates, and our families.

Our responsibilities sober us; our adversities strengthen us.

Service to God and Country is our special privilege. We serve with honor.

THE FUTURE OF THE NAVY

The Navy will always employ new weapons, new techniques, and greater power to protect and defend the United States on the sea, under the sea, and in the air.

Now and in the future, control of the sea gives the United States her greatest advantage for the maintenance of peace and for victory in war.

Mobility, surprise, dispersal, and offensive power are the keynotes of the new Navy. The roots of the Navy lie in a strong belief in the future, in continued dedication to our tasks, and in reflection on our heritage from the past.

Never have our opportunities and our responsibilities been greater.

greatly reduced. Such fields should not be planted to cotton or other susceptible summer crops without special treatment.

Fig. 2. The tap root rots leaving part of the fibrous center.

Control

If, as is often the case, the root rot infestation is concentrated in one part of the field, and the affected area is large enough to permit the use of farm machinery, the area can be replanted in October. This will not eliminate the root rot organism, but will result in good hay yields until midsummer of the following year. First, apply a two inch layer of manure, straw, spoiled hay or other organic matter to the root rot area. Then sprinkle the organic matter with ammonium sulphate and soil sulphur at the rate of one pound of each to ten square feet. Mix the applied material with the surface soil with a renovator or disc and reseed in October.

If infestation is slight or widely scattered, the above method is impractical. When the yield of hay and/or pasture is no longer profitable, plow up the alfalfa and consider alternative uses of the land. Two possibilities are:

(a) Cotton following a winter manure crop of papago peas as outlined in Root Rot Circular No. 4 which can be supplied by your county agent.

(b) At least a three year rotation with non-susceptible crops such as small grains, sorghums, or Sudan grass or winter crops such as flax, safflower, or winter vegetables. These winter crops are not resistant, but escape the disease which is relatively inactive during winter.

CHAPTER 1

AVIATION ELECTRONICS TECHNICIAN RATING

This Rate Training Manual is designed as an aid in preparing for advancement to Petty Officer Third and Second Class Aviation Electronics Technician. It is based primarily on the professional requirements as specified in the Manual of Qualifications for Advancement, NavPers 18068 (Series), through change No. 4. Therefore, subsequent changes in the qualifications may not be reflected in the information given in this training manual.

Most of the contents of this training manual involves the technical subject matter which the Aviation Electronics Technician must become proficient. Other areas covered include maintenance organization, safety, and publications.

ENLISTED RATING STRUCTURE

The present enlisted rating structure consists of general ratings and service ratings.

General ratings identify broad occupational fields of related duties and functions. Some general ratings include service ratings; others do not. Both Regular Navy and Naval Reserve personnel may hold general ratings.

Service ratings identify subdivisions or specialties within a general rating. Although service ratings can exist at any petty officer level, they are most common at the PO3 and PO2 levels. Both Regular Navy and Naval Reserve personnel may hold service ratings.

AVIATION ELECTRONICS TECHNICIAN RATING

The Aviation Electronics Technician rating, at pay grades E-4 and E-5, comprises the two service ratings ATN and ATR. At pay grades E-6 through E-8, there is a single general rating, AT. At pay grade E-9 the Aviation Electronics Technician rating loses its identify; personnel of pay grade E-8 in this rating, along with AECS, AQCS, and AXCS, advance to Master Chief Avionics Technician, AVCM. Figure 1-1 illustrates all paths of advancement for an Airman Recruit to Master Chief Avionics Technician (AVCM), Chief Warrant Officer (W-4), or to Limited Duty Officer (LDO). The advancement paths through the AT ratings are emphasized in the figure. Shaded areas indicate career stages where qualified enlisted men may advance to Warrant Officer (W-1), or selected commissioned Warrant Officers may advance to Limited Duty Officer. Additional information concerning promotion to Warrant or Commissioned Officer is presented later in this chapter.

Aviation Electronics Technicians inspect and maintain aviation electronic equipment except ASW and fire control equipment, including the following: detection, reconnaissance, identification, communication, navigation, display, and special purpose equipment; target drone and pilotless aircraft equipment; and related equipment and test equipment; and operate airborne CIC equipment.

Aviation Electronics Technician N (Radio and Radio Navigation Equipment) inspect and maintain aviation electronic identification, radio communication, and radio navigation equipment including: radio transmitting, receiving, relaying, and direction finding equipment; radio and radar altimeters; electronic interrogating and transponding equipment; distance and time difference measuring equipment; and related equipment and test equipment.

Aviation Electronics Technicians R (Radar and Radar Navigation Equipment) inspect and

13134

Figure 1-1.–Paths of advancement.

AE.1

13135

13134

maintain aviation radar and electronic identification equipment, including: radar; radar display and relay equipment; electronic interrogating and transponding equipment; and related equipment and test equipment.

As an Aviation Electronics Technician (N or R) Third Class or Second Class, your assignment possibilities cover a wide range of duties and responsibilities. Your specific duties will depend to a large extent upon the type of organization to which you are assigned. It is probable that you will be assigned to billets which are concerned with the maintenance of electronic and associated equipment within the responsibility of your service rating. As either an ATN or an ATR you may be assigned to any of the several types of aircraft maintenance activities.

In an aircraft squadron, your duties are concerned primarily with the avionics division of the maintenance department. You will work under the supervision of the avionics division chief on all routine maintenance functions and on minor repair of electronic and associated equipments. You will also perform such other duties as may be assigned to you by the avionics officer or his representative. In some squadrons you may be assigned in the capacity of plane captain.

In the aircraft maintenance department (AMD) of a naval air station, you may be assigned duties similar to those in a squadron. You may be assigned to a check crew or to a troubleshooting crew. You may be assigned to a shop for more detailed maintenance than is normally performed by the squadron level activity.

On aircraft carriers you may be assigned to a crew which aids in the incorporation of required changes and modifications in squadron aircraft or electronic equipment. You may be required to perform work involving shop tools and services. You may perform more extensive maintenance than that normally performed by the squadron.

One of the billets available to the ATN2 or ATR2 may be assignments as an instructor in a training activity. Instructor duty may be performed either as a shore duty or as a sea duty assignment. Shore duty instructor assignments in your rate and rating are normally to the Aviation Electronics Technician School at the Naval Air Technical Training Center, Millington, Tennessee. Fleet instructor billets are available at various FAETU (Fleet Airborne Electronics Training Unit) NAMTG (Naval Air Maintenance Training Group), and RCVW (Readiness Air Wing) activities.

FAETU courses are usually concerned with a specific equipment or procedure. NAMTG courses may involve specific procedures, specific equipment, or specific aircraft. RCVW courses are normally concerned with the training of personnel in the operation and maintenance of equipment in new or unfamiliar types of aircraft.

LEADERSHIP

Since you have been in pay grade E-3 or E-4 for some time, you realize that more leadership is required of the higher rates. Not only are you required to have superior knowledge, but you are also required to have the ability to handle personnel. This ability increases in importance as you advance through the various rates as a petty officer.

In General Order No. 21, the Secretary of the Navy outlined some of the most important aspects of naval leadership. By naval leadership is meant the art of accomplishing the Navy's mission through people. It is the sum of those qualities of intellect, of human understanding, and of moral character that enable a man to inspire and to manage a group of people successfully. Effective leadership, therefore, is based on personal example, good management practices, and moral responsibility. The term leadership includes all three of these elements.

The current Navy Leadership Program is designed to keep the spirit of General Order No. 21 ever before you. If the threefold objective is carried out effectively in every command, the program will make you a better leader of men in your present billet and in your future assignments. As you advance up the leadership ladder, more and more of your worth to the Navy will be judged on the basis of the amount of efficient work you obtain from your subordinates rather than how much of the actual work you do yourself.

For information on the practical application of leadership and supervision, study Military Requirements for Petty Officer 3 & 2, NavPers 10056-B.

13136

ADVANCEMENT

Some of the rewards of advancement are easy to see. You get more pay. Your job assignments become more interesting and more challenging. You are regarded with greater respect by officers and enlisted personnel. You enjoy the satisfaction of getting ahead in your chosen Navy career.

The advantages of advancement are not yours alone. The Navy also profits. Highly trained personnel are essential to the functioning of the Navy. By advancement, you increase your value to the Navy in two ways: First, you become more valuable as a person who can train others and thus make far-reaching contributions to the entire Navy; and second, you become more valuable as a technical specialist in your own rating.

HOW TO QUALIFY FOR ADVANCEMENT

What must you do to qualify for advancement? The requirements may change from time to time, but usually you must:

1. Have a certain amount of time in your present grade.
2. Complete the required military and professional training manuals.
3. Demonstrate your ability to perform all the practical requirements for advancement by completing the Record of Practical Factors, NavPers 1414/1.
4. Be recommended by your commanding officer, after the petty officers and officers supervising your work have indicated that they consider you capable of performing the duties of the next higher rate.
5. Successfully complete the applicable military/leadership examination which is required prior to participating in the advancement (professional) examination.

Some of these general requirements may be modified in certain ways. Figure 1-2 gives a more detailed view of the requirements for advancement of active duty personnel; figure 1-3 gives this information for inactive duty personnel.

Remember that the requirements for advancement can change. Check with your educational services office to be sure that you know the most recent requirements.

Advancement is not automatic. After you have met all the requirements, you are eligible for advancement. You will actually be advanced only if you meet all the requirements (including making a high enough score on the written examination) and if quotas permit.

HOW TO PREPARE FOR ADVANCEMENT

What must you do to prepare for advancement? Advancement is not an overnight affair. One does not take the advancement examination and wake up in the morning in the next pay grade. There is a path or sequence of events which one must pursue. Certain things must be done or accomplished before one is admitted to the advancement in rate examination. To prepare for advancement, you will, need to be familiar with the "Quals" Manual, the Record of Practical Factors, NavPers 1414/1. Training Publications for Advancement, NavPers 10052 (Series), and applicable Rate Training Manuals. The following sections describe them and give you some practical suggestions on how to use them in studying and preparing for the advancement in rate examination.

"Quals" Manual

The Manual of Qualifications for Advancement, NavPers 18068 (Series), gives the minimum requirements for advancement. This manual is usually called the "Quals" Manual, and the qualifications themselves are often called "quals." The qualifications are of two general types: military requirements, and professional (or technical) qualifications.

Military requirements apply to all ratings rather than to any one particular rating. Military requirements for advancement to third class and second class petty officer rates deal with military conduct, naval organization, military justice, security, watch standing, and other subjects which are required of petty officers in all other ratings.

13137

ACTIVE DUTY ADVANCEMENT REQUIREMENTS

REQUIREMENTS *	E1 to E2	E2 to E3	#† E3 to E4	# E4 to E5	† E5 to E6	† E6 to E7	† E7 to E8	† E8 to E9
SERVICE	4 mos. service—or completion of recruit training.	6 mos. as E-2.	6 mos. as E-3.	12 mos. as E-4.	24 mos. as E-5.	36 mos. as E-6. 8 years total enlisted service.	36 mos. as E-7. 8 of 11 years total service must be enlisted.	24 mos. as E-8. 10 of 13 years total service must be enlisted.
SCHOOL	Recruit Training.		Class A for PR3, DT3, PT3. AME 3, HM 3			Class B for AGC MUC, MNC.		
PRACTICAL FACTORS	Locally prepared check-offs.	Records of Practical Factors, NavPers 1414/1, must be completed for E-3 and all PO advancements.						
PERFORMANCE TEST			Specified ratings must complete applicable performance tests before taking examinations.					
ENLISTED PERFORMANCE EVALUATION	As used by CO when approving advancement.	Counts toward performance factor credit in advancement multiple.						
EXAMINATIONS**	Locally prepared tests.	See below.	Navy-wide examinations required for all PO advancements.				Navy-wide, selection board.	
NAVY TRAINING COURSE (INCLUDING MILITARY REQUIREMENTS)		Required for E-3 and all PO advancements unless waived because of school completion, but need not be repeated if identical course has already been completed. See NavPers 10052 (current edition).					Correspondence courses and recommended reading. See NavPers 10052 (current edition).	
AUTHORIZATION	Commanding Officer		U.S. Naval Examining Center			Bureau of Naval Personnel		

* All advancements require commanding officer's recommendation.
† 1 year obligated service required for E-5 and E-6; 2 years for E-6, E-7, E-8 and E-9.
\# Military leadership exam required for E-4 and E-5.
** For E-2 to E-3, NAVEXAMCEN exams or locally prepared tests may be used.

Figure 1-2.–Active duty advancement requirements.

13138

INACTIVE DUTY ADVANCEMENT REQUIREMENTS

REQUIREMENTS *	E1 to E2	E2 to E3	E3 to E4	E4 to E5	E5 to E6	E6 to E7	E8	E9
TOTAL TIME IN GRADE	4 mos.	6 mos.	15 mos.	18 mos.	24 mos.	36 mos.	36 mos.	24 mos.
TOTAL TRAINING DUTY IN GRADE †	14 days	14 days	14 days	14 days	28 days	42 days	42 days	28 days
PERFORMANCE TESTS			Specified ratings must complete applicable performance tests before taking examination.					
DRILL PARTICIPATION	Satisfactory participation as a member of a drill unit.							
PRACTICAL FACTORS (INCLUDING MILITARY REQUIREMENTS)	Record of Practical Factors, NavPers 1414/1, must be completed for all advancements.							
NAVY TRAINING COURSE (INCLUDING MILITARY REQUIREMENTS)	Completion of applicable course or courses must be entered in service record.							
EXAMINATION	Standard Exam	Standard Exam or Rating Training.	Standard Exam required for all PO Advancements.		Standard Exam, Selection Board. Also pass Mil. Leadership Exam for E-4 and E-5.			
AUTHORIZATION	Commanding Officer		U.S. Naval Examining Center		Bureau of Naval Personnel			

* Recommendation by commanding officer required for all advancements.

† Active duty periods may be substituted for training duty.

Figure 1-3.–Inactive duty advancement requirements.

13139
13139

Professional qualifications are technical or professional requirements that are directly related to the work of each rating.

Both the military requirements and the professional qualifications are divided into subject matter groups; then, within each subject matter group, they are divided into practical factors and knowledge factors. Practical factors are things you must be able to DO. Knowledge factors are things you must KNOW in order to perform the duties of your rate.

The qualifications for advancement and a bibliography of study materials are available in your educational services office. Study these qualifications and the military requirements carefully. The written examination for advancement will contain questions relating to the knowledge factors and the knowledge aspects of the practical factors of both the military requirements and the professional qualifications. If you are working for advancement to second class, remember that you may be examined on third class qualifications as well as on second class qualifications.

The "Quals" Manual is kept current by means of changes which occur from time to time. Never trust any set of "quals" until you have checked the change number against an up-to-date copy of the "Quals" Manual. Be sure you have the latest revision.

Record of Practical Factors

Before you can take the Navy-wide examination for advancement, there must be an entry in your service record to show that you have qualified in the practical factors of both the military requirements and the professional qualifications. A special form known as the Record of Practical Factors, NavPers 1414/1 is used to keep a record of your practical factor qualifications. The form lists all practical factors, both military and professional. As you demonstrate your ability to perform each practical factor, appropriate entries are made in the DATE and INITIALS columns.

Changes are made periodically to the Manual of Qualifications for Advancement and revised forms of NavPers 1414/1 are provided when necessary. Extra space is allowed on the Record of Practical Factors for entering additional practical factors as they are published in changes. The Record of Practical Factors also provides space for recording demonstrated proficiency in skills which are within the general scope of the rate but which are not identified as minimum qualifications for advancement.

If you are transferred before you qualify in all practical factors, NavPers 1414/1 should be forwarded with your service record to your next duty station. You can save yourself a lot of trouble by making sure that this form is actually inserted in your service record before you are transferred. If the form is not in your service record, you may be required to start all over again and requalify in the practical factors which have already been checked off.

A second copy of the Record of Practical Factors should be made available to each man in pay grades E-2 through E-8 for his personal record and guidance.

NAVPERS 10052

Training Publications for Advancement, NavPers 10052 (Series), is a very important publication for anyone preparing for advancement. This bibliography lists required and recommended Rate Training Manuals and other reference material to be used by personnel working for advancement. NavPers 10052 is revised and issued once each year by the Bureau of Naval Personnel. Each revised edition is identified by a letter following the NavPers number. When using this publication, be sure that you have the most recent edition.

If extensive changes in qualifications occur between the annual revisions of NavPers 10052, a supplementary list of study material may be issued in the form of a BuPers Notice. When you are preparing for advancement, check to see whether changes have been made in the qualifications. If changes have been made, see if a BuPers Notice has been issued to supplement NavPers 10052.

The required and recommended references are listed by rate level in NavPers 10052. If you are working for advancement to third class, study the material that is listed for third class. If you are working for advancement to second class, study the material that is listed for second class. Remember that you are also responsible for the references listed at the third class level.

1015140

In using NavPers 10052, you will notice that some Rate Training Manuals are marked with an asterisk (*). Any manual marked in this way is MANDATORY–that is, it must be completed at the indicated rate level before you are eligible to take the Navy-wide examination for advancement. Each mandatory manual may be completed by passing the appropriate enlisted correspondence course that is based on the mandatory training manual; passing locally prepared tests based on the information given in the training manual, or in some cases, successfully completing an appropriate Class A school.

Do not overlook the section of NavPers 10052 which lists the required and recommended references relating to the military requirements for advancement. All personnel must complete the mandatory military requirements training manual for the appropriate rate level before they can be eligible to advance.

The references in NavPers 10052 which are recommended, but not mandatory, should also be studied carefully. All references listed in NavPers 10052 may be used as source material for the written examinations at the appropriate rate levels.

Rate Training Manuals

There are two general types of Rate Training Manuals. Rating manuals (such as this one) are prepared for most enlisted rates, giving information that is directly related to the professional qualifications. Basic manuals give information that applies to more than one rate and rating.

Rate Training Manuals are revised from time to time to keep them up to date technically. The revision of a Rate Training Manual is identified by a letter following the NavPers number. You can tell whether any particular copy of a Rate Training Manual is the latest edition by checking the NavPers number and the letter following this number in the most recent edition of List of Training Manuals and Correspondence Courses, NavPers 10061. (NavPers 10061 is actually a catalog that lists current training manuals and correspondence courses; you will find this catalog useful in planning your study program.)

Rate Training Manuals are designed to help you prepare for advancement. The following suggestions may help you to make the best use of this manual and other Navy training publications when you are preparing for advancement.

1. Study the military requirements and the professional qualifications for your rate before you study the training manual, and refer to the "quals" frequently as you study. Remember, you are studying the training manual in order to meet these "quals."

2. Set up a regular study plan. If possible, schedule your studying for a time of day when you will not have too many interruptions or distractions.

3. Before you begin to study any part of the training manual intensively, become familiar with the entire manual. Read the preface and the table of contents. Check through the index. Look at the appendixes. Thumb through the manual without any particular plan, looking at the illustrations and reading bits here and there as you see things that interest you.

4. Look at the training manual in more detail, to see how it is organized. Look at the table of contents again. Then, chapter by chapter, read the introduction, the headings, and the subheadings. This will give you a clear picture of the scope and content of the manual. As you look through the manual in this way, ask yourself some questions: What do I need to learn about this? What do I already know about this? How is this information related to information given in other chapters? How is this information related to the qualifications for advancement?

5. When you have a general idea of what is in the training manual and how it is organized, fill in the details by intensive study. In each study period, try to cover a complete unit–it may be a chapter, a section of a chapter, or a subsection. If you know the subject well, or if the material is easy, you can cover quite a lot at one time. Difficult or unfamiliar material will require more study time.

6. In studying any one unit–chapter, section or subsection–write down the questions that occur to you. Many people find it helpful to make a written outline of the unit as they study, or at least to write down the most important ideas.

7. As you study, relate the information in the training manual to the knowledge you already have. When you read about a process, a skill, or a situation, try to see how this information ties in with your own past experience.

04 13141

8. When you have finished studying a unit, take time out to see what you have learned. Look back over your notes and questions. Maybe some of your questions have been answered, but perhaps you still have some that are not answered. Without referring to the training manual, write down the main ideas that you have learned from studying this unit. Do not quote the manual. If you cannot give these ideas in your own words, the chances are that you have not really mastered the information.

9. Use Enlisted Correspondence Courses whenever you can. The correspondence courses are based on Rate Training Manuals or on other appropriate texts. As mentioned before, completion of a mandatory Rate Training Manual can be accomplished by passing an Enlisted Correspondence Course based on the Rate Training Manual. You will probably find it helpful to take other correspondence courses, as well as those based on mandatory training manuals. Taking a correspondence course helps you to master the information given in the training manual, and also helps you see how much you have learned.

10. Think of your future as you study Rate Training Manuals. You are working for advancement to third class or second class right now, but someday you will be working toward higher rates. Anything extra that you can learn now will help you both now and later.

SOURCE OF INFORMATION

One of the most useful things you can learn about a subject is how to find out more about it. No single publication can give you all the information you need to perform the duties of your rating. You should learn where to look for accurate, authoritative, up-to-date information on all subjects related to the military requirements for advancement and the professional qualifications of your rating.

Some of the publications described in this manual are subject to change or revision from time to time–some at regular intervals, others as the need arises. When using any publication that is subject to change or revision, be sure that you have the latest edition. When using any publication that is kept current by means of changes, be sure you have a copy in which all official changes have been made. Studying canceled or obsolete information will not help you perform efficiently or to advance; it is likely to be a waste of time, and may even be seriously misleading.

13142

CHAPTER 2

AIRCRAFT MAINTENANCE ORGANIZATION

In order to maintain increasingly complex aircraft in their prime operating condition various aircraft maintenance organizations and procedures have been employed throughout the Navy. Prior to and during World War II, it was a general practice for every operating activity to have its own maintenance spaces, equipment, and a complement of maintenance personnel to accomplish all maintenance except overhaul. Due to variance in workload between squadrons, some shops were idle at times and could have been used by maintenance personnel from other squadrons on the same station to accomplish their work.

A combining of talents, efforts, facilities, and equipments for the accomplishment of common tasks was indicated. Through the process of evolution, combining of naval aircraft maintenance personnel and consolidation of maintenance facilities were effected on a Navy-wide basis when the Naval Aircraft Maintenance Program (NAMP) was established.

NAVAL AIRCRAFT MAINTENANCE PROGRAM

The Naval Aircraft Maintenance Program was designed to insure maximum utilization of manpower, material, and equipment and establish standard maintenance procedures and organizations for the accomplishment of maintenance on naval aircraft and associated equipment. The adoption of standard organizations and procedures promotes a high degree of uniformity among all activities in the methods that are used to manage and utilize maintenance personnel, material, and facilities. It results in a decrease in time required to indoctrinate recently assigned personnel.

13143

The improvement of aircraft readiness is of utmost importance; costly, complex weapons systems and spares demand maximum command attention to the repair of critical items to enable aircraft to be in a ready status. It is therefore mandatory that all maintenance personnel have a thorough knowledge of and abide by the established procedures.

LEVELS OF MAINTENANCE

The task of maintaining naval aircraft in an operationally ready condition ranges from a few minutes of squadron servicing to months of overhaul in a depot level maintenance activity. To more efficiently accomplish maintenance on military aircraft the present concept is to divide the maintenance functions into three distinct levels–depot, intermediate, and organizational. The determination of what maintenance will be performed at each level is governed primarily by the availability and distribution of maintenance equipment and facilities.

Each command and support agency is responsible for continually reviewing the distribution of equipment and facilities to insure that the amount of maintenance performed at the lowest levels is consistent with available skills and personnel.

Organizational Maintenance

Organizational maintenance is the type of work performed by the operating squadron or unit on a day-to-day basis in support of its own operations. Maintenance performed at this level includes (1) inspection, (2) servicing, (3) handling, (4) "on-aircraft" corrective maintenance, including removal and installation of parts and

EUONYMUS POWDERY MILDEW

Powdery mildew on evergreen Euonymus is an unsightly pest and is prevalent in many plantings in Arizona. The disease is caused by the fungus Erysiphe euonymus. Spores which are carried by the wind spread the organism from planting to planting.

Symptoms - The fungus infects leaves of Euonymus and forms a thick white to gray felt on the leaf surface. Some yellowing and defoliation may result.

Control - Sprays of Actidione PM give good control and may be used in hot weather. Follow the label directions. Sulphur dust is also effective, but will burn the foliage when temperatures are above 90°F.

Fig. 1. Mildew may be in scattered spots or covering nearly the entire leaf surface.

Fig. 2. New growth may be severely attacked.

Note: The information given herein is supplied with the understanding that no discrimination is intended and no indorsement by the Arizona Extension Service is implied.

components, (5) complying with technical directives (when prescribed), and (6) the necessary recordkeeping and reports peculiar to organizational maintenance.

Organizational maintenance in an operating activity is performed by permanently assigned personnel who are not responsible for intermediate maintenance. Organizational maintenance at shore stations (on aircraft assigned to the station) normally is a function of the Operations Maintenance Division (OMD). The OMD also provides organizational maintenance and such other assistance to transiting aircraft as may be directed by higher authority.

Intermediate Maintenance

Intermediate maintenance is that type of work performed in centrally located facilities for the support of operating activities within a designated geographical area, at a particular base or station, or aboard aviation ships. This level of maintenance is assigned for performance to such units as Station or Ships Aircraft Intermediate Maintenance Departments (AIMD), Marine Headquarters and Maintenance Squadrons, etc. Typical of the work performed at this level is shop type repair and test work on aircraft components and equipment from the supported units. Technical assistance, when required, is furnished by personnel of the intermediate maintenance facility to the supported operating activities.

Intermediate maintenance activities are normally manned by a nucleus of permanently assigned personnel and certain designated intermediate maintenance personnel temporarily assigned from the on-board tenant squadrons. When these squadrons deploy from their home stations, their intermediate maintenance personnel accompany them, and are then temporarily assigned to the AIMD if afloat or at their new station.

Depot Maintenance

Depot maintenance is that type of work normally accomplished in an industrial type facility (Naval Air Rework Facilities or contractors' plants.) This level includes overhaul and major repair or modification of aircraft, components, and equipments. It also includes the manufacture of specified aeronautical parts to be stocked as spares and the manufacture of kits for the accomplishment of aircraft and equipment modification. Installation of these spare-parts kits may be done at this or a specific lower level of maintenance.

Navy Depot maintenance activities are manned primarily by civilians. However, some military personnel are usually assigned and assist with the intermediate and organizational type work necessarily connected with the depot facility.

It can be seen from the foregoing that the three aircraft maintenance levels or categories provide for an orderly separation of the various maintenance tasks. The bases for the separation are complexity of the task, equipment and space requirements, the skill level of assigned personnel, and the scope of support responsibility.

AIRCRAFT MAINTENANCE DEPARTMENT ORGANIZATION

The organization for Aircraft Maintenance Departments provide firm lines of authority from the maintenance officer to personnel accomplishing the work for which the department is responsible. The term "department" used in this training manual is used as a general term which applies fully to all maintenance activities having a department head. In cases of maintenance activities assigned as divisions to other departments, the next echelon (division) is used in place of department. Branches become sections, and sections become units.

Major segments of the department are called divisions. Divisions are subdivided into branches and branches are subdivided into sections if necessary. The aircraft maintenance officer manages the department and is responsible to the commanding officer for the accomplishment of the department's mission.

The Aircraft Maintenance Department supports naval operations by the upkeep of assigned and supported aircraft and associated support equipments to the level and depth of maintenance assigned. Specific functions include the following:

1. Periodic maintenance and routine inspection and servicing of aircraft, associated

13144

support equipment, and aeronautical material and components including the necessary disassembly, cleaning, examination, repair, modification test, inspection, assembly, and preservation.

2. Special work in compliance with technical directives or local instructions.

3. Correction of discrepancies.

4. Assurance of high quality of all work.

5. Maintenance of records and technical publications.

6. Maintenance and custody of tools and other organizational equipment.

7. Training of assigned personnel.

8. Conduct maintenance and ground handling safety programs.

INTERMEDIATE LEVEL ACTIVITY

The primary purpose of intermediate level maintenance is to support and supplement the work of organizational maintenance activities. These functions are normally performed in centrally located areas for the support of operating aircraft on a shore station, aboard a ship, or within a designated area.

The responsibility for intermediate level maintenance is assigned to station aircraft maintenance departments ashore and aircraft intermediate maintenance departments afloat and encompasses the following:

1. Repair and test of aircraft components requiring shop facilities not available in a lower level maintenance activity.

2. Aircraft changes and modifications.

3. Reporting and keeping of records.

Figure 2-1 illustrates an intermediate level maintenance department afloat with their respective work center code numbers.

Figure 2-2 illustrates an intermediate level maintenance department (shore), including work center code numbers. As can be seen in the figure, the activity is composed of staff and production divisions.

Maintenance/Material Control Officer

The Maintenance Material Control Officer is directly responsible to the Maintenance Officer for the management of the overall productive effort of the department. His general responsibilities include but are not limited to the following:

1. Scheduling, coordinating, and monitoring the workload of the department.

2. Maintaining liaison with supported/supporting activities and the local supply department to insure material requirements are fulfilled in order to keep productive capacity compatible with workload requirements.

3. Coordinating the order, receipt, and delivery of material, the administrative screening, scheduling, and control of processed components, and the control and usage of funds provided the department.

In discharging the duties of production control, the Maintenance/Material Control Officer will perform the following:

1. Plan and schedule the workload so as to insure maximum utilization of personnel, material, and resources.

2. Coordinate the actions of the production divisions to insure prompt movement of components through the department.

3. Assign production control numbers, work priorities, due-in and due out dates to the various work centers, and establish maintenance control procedures in order to effectively monitor the daily workload requirements.

4. Maintain technical directive control procedures for the department.

5. Review and approve work requests from supported activities.

6. Maintain files of completed maintenance action forms and work requests (6 months).

7. Maintain the Intermediate Maintenance Control Register.

8. Recommend and control cannibalization in accordance with applicable directives.

9. Submit reports as applicable.

10. Analyze daily and monthly maintenance data reports to ascertain effective utilization of personnel resources.

An assistant to the Maintenance/Material Control Officer will discharge the duties of material control by performing the following:

1. Plan, requisition, and expedite materials to enable the department to perform its mission quickly and effectively.

2. Pass all requirements for material for support of weapons system maintenance to the supporting SSC (Supply Support Center), and maintain a material control register for these items.

NOTES:

(1) AND (2) THE AIRCRAFT MAINTENANCE DEPARTMENT OFFICER (AFLOAT), DEPENDENT UPON HIS SENIORITY, WILL BE ASSIGNED AS EITHER THE INTERMEDIATE MAINTENANCE OFFICER OR MAINTENANCE/MATERIAL CONTROL OFFICER FOR CUSTODY/CONTINUITY PURPOSE UPON DEBARKATION OF THE AIR WING.

(3) BRANCH OFFICERS WILL BE TAD FROM AIR WING/GROUP TO THE IMA FOR MANAGEMENT RESPONSIBILITIES.

AT.1

Figure 2-1.–Intermediate level maintenance department organization, afloat.

NOTES: (1) WHEN ASSIGNED

(2) QUALIFICATION WILL BE PERFORMED BY THE TEST EQUIPMENT BRANCH OF THE AVIONICS DIVISION

AT.2

Figure 2-2.–Intermediate maintenance department, shore.

13146

3. Establish delivery-pickup points for all material as mutually agreed upon by the Supply and Maintenance Officers. Insure that material received is expeditiously routed to the applicable work center.

4. Furnish technical advice and information to the supply activity on the identity and quantity of supplies, spare parts, and materials required for maintenance actions.

5. Establish procedures to insure the periodic inventory of tools and the adequate accountability of material and equipment.

6. Initiate surveys in the event of loss, damage, or destruction of accountable material.

7. Keep the Maintenance/Material Control Officer advised of the overall supply situation as it affects the department.

8. Verify Aircraft on Work Stoppage (AOWS) requisitions and prepare necessary reports in accordance with chapter IV of the 3-M Manual.

9. Perform cost and allotment record accounting, charting, and budgeting of costs applicable to the department.

10. Monitor the operation of toolrooms and maintain an updated IMRL (Individual Material Readiness List).

11. Arrange for return of prospective F condition of R/S material and locally repaired RFI material to supply.

12. Operate an administrative screening unit in accordance with chapter IV of the 3-M Manual.

13. Retain material within the department that is in AWP status until such time the requisition is filled and continually ascertain followup status on same.

Staff Division

Staff divisions are incorporated into the framework of aircraft maintenance activities for the purpose of providing services and support to the production divisions. A discussion of some of the more important functions of the staff divisions is contained in the following paragraphs:

ANALYSIS DIVISION.–The Analysis Division provides qualitative and quantitative analysis information to the Maintenance Officer in order to enable him to continually review the management practices within his organization by accomplishing the following functions:

1. Managing, coordinating, and monitoring the MDCS (Maintenance Data Collection System) for the department.

2. Reviewing MDR (Maintenance Data Reports) to discover and point out workload inequities, personnel inequities, and resource inequities.

3. Collecting, reviewing, and delivering source documents to data services for processing. Picking up complete data reports and disseminating throughout the organization.

4. Maintaining an adequate supply of manuals, source documents, registers, etc., on hand to insure continuity in the MDCS.

5. Developing an analytical plan which encompasses all maintenance functions to provide periodic audits of work center performance.

6. Developing charts, graphs, and displays for command presentations.

7. Maintaining an updated master roster for the department.

8. Coordinating and insuring that 3-M training services are provided to assigned personnel.

ADMINISTRATION DIVISION.–The standard organization structure for intermediate maintenance activities provides an administration division. (In activities where organizational is the highest level of maintenance performed, the organization structure does not provide for a separate administration division. In such activities the functions of the administration division are the responsibility of the Assistant Aircraft Maintenance Officer.)

Administration division personnel accomplish the following specific functions:

1. Establish and control a central reporting and record keeping system for all maintenance reports and correspondence.

2. Implement all directives concerning distribution, retention, and disposition of records and reports.

3. Provide clerical and administrative services for the department.

4. Reproduce as necessary and distribute incoming messages and other data.

5. Supervise and coordinate department administrative responsibilities with other departments/divisions as required.

13147

6. Conduct liason with the Activity's Administration Department regarding department personnel matters.

7. Safeguard and distribute personal mail to department personnel, when appropriate.

8. Make proper distribution of all non-technical information and publications.

9. Distribute approved locally issued maintenance instructions, reports, and studies.

10. Control classified material (excluding technical manuals and letter type directives) required by the department.

11. Establish and coordinate the department training requirements. Obtain necessary school quotas to support these requirements.

12. Determine requirements for and insure establishment of proper transportation and communication systems to provide complete support of the workload.

13. Assign spaces to the various divisions and establish the responsibility for security and cleanliness of such spaces.

14. Assume responsibility for the cleanliness and security of vacant or unassigned aircraft maintenance spaces.

15. Arrange department participation in joint inspections of facilities assigned to tenant activities especially incident to the departure of a tenant activity.

QUALITY ASSURANCE DIVISION.–The Quality assurance division provides the department head with the quality status of work accomplished, points up areas that need particular attention, and develops more realistic inspection requirements. Primary functions performed by this division are as follows:

1. Review all incoming technical publications and directives affecting the department to determine their application to quality assurance.

2. Prepare or assist in the preparation of maintenance instructions to insure that proper direction and emphasis is given to implementing quality assurance.

3. Maintain the master technical library for the department, including letter type technical directives and control classified technical publications for the department. Insure that each division/branch receives all publications applicable to its work areas and that these are kept current and complete. Where applicable, maintain the Reader-Printer and associated equipment for aircraft models supported.

4. Establish qualification requirements for Quality Assurance Representatives and Collateral Duty Inspectors. Review the qualifications of personnel nominated for these positions and endorse nominations to the Commanding Officer via the department head. Maintain a current record of all designated inspectors. Periodically promulgate a list of all designated inspectors by TIMI or command notice.

5. Obtain and utilize appropriate inspection equipment such as lights, mirrors, magnifying glasses, dye penetrant kits, pressure gages, etc. Insure that productive personnel have such equipment available and in use.

6. Periodically accompany Collateral Duty Inspectors on assigned inspections and recheck their qualifications.

7. Insure all work guides, checkoff lists, checksheets, maintenance requirement cards, etc., used to define or control maintenance operations are completed and current prior to issuing to crews/individuals.

8. Review all UR entries, explanations and descriptions to insure they are accurate, clear, concise and comprehensive prior to mailing. Additionally, the technician preparing the UR and either the Quality Assurance or Maintenance Officer must sign the completed UR.

9. Cause to be inspected all equipment received for use, returned for repair, or held awaiting repair to insure its material condition, identification, packaging, preservation, and configuration are satisfactory and, when applicable, that shelf life limits are not exceeded.

10. Perform inspections of maintenance equipment and precision measuring equipment to insure compliance with calibration and safety instructions.

11. Perform technical inspections of all maintenance equipment and facilities.

12. Provide for the continuous on-the-job training of all inspectors in the techniques and procedures pertaining to the conduct of inspections.

13. When directed or required, provide technical task forces to study trouble areas and submit recommendations for corrective action.

14. Maintain adequate records and data on discrepancies to enable establishment of trends

13148

with the specific objective of determining when discrepancies in any area are ascending.

15. Maintain liaison with contractor, NAESU, NavAirSysComRep's, and other available field technical services. Establish and maintain liaison with other maintenance activities and rework points in order to obtain information on ways for improving maintenance techniques, quality of workmanship and quality assurance procedures.

16. Review maintenance data reports and note unnecessary and/or recurring discrepancies requiring special action.

17. Insure that established standard procedures are observed by production personnel when conducting bench checks, tests, and repairs of components including engines. Periodically check the performance of this work to insure the desired quality level is obtained.

18. Insure the configuration of aircraft components and support equipment is such that all essential/applicable modifications have been incorporated. This necessitates the review of appropriate records.

Production Divisions (Intermediate Level)

Maintenance of naval aircraft involves the actual performance of maintenance tasks by ordnancemen, mechanics, and technicians. The production divisions are manned by such personnel. Although each production division is broken down into work centers, which, on an organizational chart, are shown as the lowest element, this is not in keeping with their importance. If it were not for the production divisions and work centers, there would be no reason for the existence of any other part of the organization.

Intermediate maintenance level production divisions, such as are in AIMD's, are generally manned by personnel of the same rating. In organizational maintenance activities, some divisions are made up of personnel from several ratings. The type of work usually performed by an individual is the same regardless of the maintenance level at which he is working; ie., AD's work on engines, AQ's work on fire control equipment, ordnancemen work on armament equipment, etc. The difference between the work performed in production elements at various levels lies in the depth of maintenance performed.

The standard organization framework for intermediate level maintenance activities provides for six production divisions. (See fig. 2-1 or fig.2-2). The production divisions provide intermediate level maintenance on aircraft components and equipment for the supported activities. Some of the more important responsibilities and functions of these divisions are described in the following paragraphs.

POWERPLANTS.–The powerplants division is manned by Aviation Machinist's Mates who perform maintenance on powerplants, powerplant components, and associated systems.

AIRFRAMES.–Aviation Structural Mechanics are assigned to work centers in the airframes division. This division is responsible for the specified level of maintenance of the airframe and structural components; movable structures and surface including their hydraulic and pneumatic control and actuating systems and mechanisms; air-conditioning, pressurization, visual improvement, oxygen, and other utility systems; and seat and canopy ejection systems and components.

AVIONICS.–The avionics division is manned with the necessary combination of the following ratings of avionics equipment for the supported activities.

The Aviation Electrician's Mates maintain aircraft electrical and instrument systems.

The Aviation Electronics Technicians maintain and test aviation electronic equipment including detection, reconnaissance, identification, communication, navigation, display, and special purpose equipment.

The Aviation Antisubmarine Warfare Technicians maintain and test aircraft antisubmarine warfare (ASW) systems and equipment, including those related to magnetic anomaly detection, long and short-range underwater detection, nuclei detection, integrated displays, and associated ASW equipments.

Aviation Fire Control Technicians maintain and test aircraft armament control systems, including fire control, and bomb director systems.

AVIATORS' EQUIPMENT.–Aircrew Survival Equipmentmen are assigned to the aviators' equipment division. This division is responsible

13149

for intermediate level maintenance as required in connection with parachutes, liferafts, life-vests, pressure suits, oxygen masks, emergency equipment kits, flight clothing, oxygen regulators, automatic parachute actuators, aviators' protective helmets, etc. AME's may also be assigned to this division for the upkeep and support of the oxygen system, pressurization and air-conditioning systems, and other emergency equipment as assigned within the scope of that rating.

ARMAMENT EQUIPMENT.–Aviation Ordnancemen are assigned to the armament equipment division and are responsible for the maintenance of aircraft armament equipment and aviation ordnance equipment.

SUPPORT EQUIPMENT.–The Aircraft Support Equipment Technician (AS) performs the necessary maintenance on the support equipment assigned to the maintenance department and supported activities. Support equipment includes, but it not limited to, such items as test stands, workstands, mobile electric powerplants, pneumatic and hydraulic servicing equipment.

ORGANIZATIONAL LEVEL ACTIVITY

The responsibility for organizational level maintenance is assigned to operating units on a day-to-day basis–to support their own operations. Maintenance performed at this level includes aircraft servicing, aircraft inspections, minor adjustments, removal and replacement of defective parts and components, limited aircraft changes and modifications, recordkeeping, and reports. Figure 2-3 illustrates an organizational level maintenance department, including work center code numbers.

Maintenance/Material Control Officer

The Maintenance/Material Control Officer performs the following functions:

1. Scheduling, coordinating, and monitoring the workload of the department.
2. Maintaining liaison with the supporting activities and the local supply department to insure material requirements are fulfilled in order to keep productive capacity compatible with workload requirements.
3. Coordinating the ordering, receipt, and delivery of material, the administrative screening, scheduling, and control of processed components, and the control and usage of funds provided the department.

In discharging the duties of production control the Maintenance/Material Control Officer will:

1. Plan and schedule the workload so as to insure maximum utilization of personnel, material, and resources.
2. Assign job control numbers for each reported discrepancy.
3. Maintain the organizational maintenance control register (3 months).
4. Maintain an up-to-date status board.
5. Provide the Operations Department with required aircraft status and configuration information.
6. Maintain technical directive control procedures.
7. Relay discrepancies to work centers with complete information as to status, by the fastest method (i.e., telephone, intercommunications, etc).
8. Review and approve work requests to the supporting activity. (Maintain completed files.)
9. Recommend and control cannibalization in accordance with applicable directives.
10. Submit reports as required.
11. Receive certain completed source documents from work centers and:
    a. Update aircraft and equipment logs, accessory record cards, configuration forms, and associated documents.
    b. Forward complete forms to data analysis.
12. Receive complete source documents from data analysis after processing and file for historical records.
13. Conduct monthly maintenance meetings and publish a monthly maintenance plan.
14. Schedule all periodic and special inspections and insure maintenance test flights are conducted in accordance with applicable instructions.

In discharging the duties of material control, he will perform those applicable functions specified previously under intermediate level maintenance as well as the following:

1. Prepare documents for material required for operational support of weapon sys-

1012150

NOTE:

(1) When responsibilities relative to operation and maintenance of ground support equipment are extensive, the Commanding Officer will establish a Ground Support Equipment Branch under the Line Division to coordinate and/or carryout organizational maintenance functions on assigned support equipment.

(2) When assigned.

Figure 2-3.–Organizational maintenance department.

AT.3

tems (i.e., material chargeable to BRAVO funds such as fuel, oil, and flight clothing, etc.) and material carried in SERVMART/JETMART outlets.

2. Verify NORSAIR (Not Operationally Ready Supply Aviation Item Report) requisitions and maintain (by BUNO) current NORSAIR status records.

3. Inventory aircraft upon receipt and transfer. Insure inventory logs entries are updated, authenticated and corrected.

Staff Divisions

The organizational level activity has only two staff divisions, having no administration division as explained under the intermediate level. The analysis division is the same for both activities; therefore, it is not discussed here. The Quality Assurance Division is the same as discussed for the intermediate level with the following additions:

1. Review "yellow sheets", maintenance data reports, periodic inspection records and note unnecessary and/or recurring discrepancies that may require special action.

2. Insure that standard established practices are observed for conducting ground tests, preflight, postflight, and daily inspections. Periodically accompany check crews, plane captains, or pilots during inspection (minimum, once a quarter).

Oc 164 51

3. Insure that pilots/crew are briefed prior to each test flight so that purpose and objectives are clearly understood.

4. Maintain current the Type Commander Maintenance Index Record.

Production Divisions

The organizational level activity provides three production divisions, which are subdivided into branches. Each of these branches/divisions performs many maintenance tasks in order for the operating unit to accomplish its assigned mission.

AIRCRAFT DIVISION.–The Aircraft Division is responsible for the accomplishment of the following functions:

1. Supervise, coordinate, and complete periodic maintenance and inspections. (Check crew leaders and such other personnel authorized by the Maintenance Officer will be permanently assigned.) Additional personnel required to perform periodic maintenance and inspections will be made available as required from other production divisions. The Maintenance/Material Control Officer is responsible for insuring that divisions assign qualified personnel for the completion of scheduled maintenance and inspections.

2. As directed by the Maintenance Officer and in conjunction with other production divisions, perform those applicable organizational maintenance functions in those areas relative to assigned branches; i.e., Airframes, Power Plants and Aviators Equipment.

3. Continuously advise the Maintenance/Material Control Officer of the status of work in progress.

4. Insure cleanliness of hangar and assigned spaces.

5. Nominate personnel for assignment as collateral duty inspectors.

6. Initiate requests for maintenance material.

7. Assume custody for tools and support equipment assigned to the Aircraft Division.

8. Interpret applicable directives and prepare, in draft form, maintenance instructions to implement such directives.

9. Recommend changes in techniques to promote maximum ground safety, safety of flight, and operational readiness of aircraft.

10. Carry out an active program for FOD (foreign object damage) control, as established by the Line Division Officer.

11. Initiate requests to maintenance/material control for job control numbers.

12. Provide troubleshooters and aircrew members, as required, and exercise technical supervision over such personnel.

13. Expedite the accomplishment of assigned work through the continuous evaluation of methods and procedures, and incorporate new techniques as appropriate.

AVIONICS/ARMAMENT DIVISION.–The Avionics/Armament Division is responsible for the accomplishment of the following functions:

1. Assign personnel required to accomplish scheduled periodic maintenance and inspections of assigned aircraft. (The Aircraft Division is responsible for the supervision, coordination, and completion of periodic maintenance and inspections.)

2. As directed by the Maintenance Officer and in conjunction with other production divisions, perform those applicable organizational maintenance functions in those areas relative to assigned branches, i.e., Electronics, Electrical/Instrument, Armament, and Reconnaissance/Photographic.

3. Continuously advise the Maintenance/Material Control Officer of the status of work in progress.

4. Insure cleanliness of assigned spaces.

5. Assume custody and accountability for assigned tools and support equipment.

6. Initiate requests for maintenance material.

7. Nominate qualified individuals for assignment as collateral duty inspectors.

8. Interpret applicable directives and prepare, in draft form, maintenance instructions to implement such directives.

9. Recommend changes in methods and techniques to promote maximum ground safety, safety of flight, and operational readiness of aircraft.

10. Initiate requests to maintenance/material control for job control numbers.

11. Provide troubleshooters and aircrew members, as required, and exercise technical supervision over such personnel.

12. Expedite the accomplishment of assigned work by continuous evaluation of methods

13152

procedures and incorporate new techniques as appropriate.

LINE DIVISION.–The Line Division is responsible for the accomplishment of the following functions:

1. Assign personnel, as required, to accomplish periodic maintenance and inspections of assigned aircraft. (The Aircraft Division is responsible for the supervision, coordination, and completion of periodic maintenance and inspections.)

2. As directed by the Maintenance Officer and in conjunction with other production divisions, perform those applicable organizational maintenance functions in those areas relative to assigned branches; i.e., plane captains, troubleshooters, and ground support equipment (when established).

3. Coordination and direction of troubleshooters. Although troubleshooters will normally be assigned from other division on a daily basis, the Maintenance Officer may assign personnel permanently to a Troubleshooter Branch of the Line Division. A troubleshooter should accomplish correction of minor discrepancies.

4. Initiate requests to maintenance/material for job control numbers.

5. Provide to pilots/aircrews records of aircraft discrepancies and corrective actions for the preceding 10 flights of the aircraft.

6. Administer the plane captain program.

7. Nominate qualified personnel as collateral duty inspectors.

8. Participate in an active FOD (foreign object damage) prevention program.

9. Initiate requests for maintenance material.

10. Insure the cleanliness of assigned aircraft and spaces.

11. Assume custody and accountability for tools and aircraft maintenance support equipment assigned to the division/branch.

12. Insure the security and proper ground handling of aircraft and associated support equipment.

13. Recommend changes in methods and techniques to promote maximum ground safety, safety of flight, and operational readiness of assigned aircraft and associated support equipment.

NAVY MAINTENANCE AND MATERIAL MANAGEMENT (3-M) SYSTEM

The 3-M system is a program to insure the highest state of aircraft readiness and reliability at the lowest cost in men, money, and material. In accomplishing this, it must insure that maintenance personnel, equipment, and facilities are utilized to the fullest extent in the performance of maintenance and not wasted in other functions not requiring highly trained maintenance skills nor specialized and expensive maintenance equipment and facilities.

All aircraft weapon systems must be maintained to the maximum extent possible to perform 100 percent of the functions for which they were designed and to accomplish the assigned mission. Anything short of this goal is considered a compromise to readiness which cannot be afforded.

By analyzing maintenance costs and devising techniques to reduce cost wherever and whenever possible, many procedures and unnecessary actions can be minimized or eliminated entirely. Therefore, by doing away with the unnecessary, effort can be concentrated on increased readiness. The 3-M system embraces two broad areas–a Planned Maintenance System, and a Maintenance Data Collection System.

PLANNED MAINTENANCE SYSTEM

The Planned Maintenance System (PMS) is a system of maintenance planning and control that provides for the uniform accomplishment of planned preventive, rather than corrective, maintenance in all aircraft squadrons. A set of Maintenance Requirement Cards (MRC's) is provided for each type of aircraft, based on information in the Periodic Maintenance Requirements Manual (PMRM). The MRC's tell what inspections are to be performed, when and how they are to be performed, the skills, tools and equipment needed, the safety precautions to be observed, and the inspection sequence.

Many separate but interrelated functions and tasks combine to make up the maintenance workload that is required for support of modern aircraft. The times allocated and available for the accomplishment of this maintenance does not

13153

20 OF 327

ED

056 238

MICROCOPY RESOLUTION TEST CHART
NATIONAL BUREAU OF STANDARDS-1963-A

allow for all of these tasks to be considered, planned, and performed on an individual basis; therefore, it is necessary that they be combined, sequenced, and phased in the proper order if the overall task is to be accomplished in the most efficient manner. The best possible use of allocated time, manpower, materials, and funds is mandatory if the maximum potential weapons system availability and utilization are to be realized.

Operating aircraft are subject to a variety of stresses, strains, vibrations, and environments. If not inspected regularly for all defects, the aircraft would soon become inoperable. The correcting of discrepancies and timely lubrication are performed in conjunction with inspections and enable the aircraft to be flown safely until the next inspection.

The most frequent types of inspections which are performed by activities responsible for the maintenance of naval aircraft are described in the following paragraphs.

Daily Inspection

Daily inspections are accomplished between the last flight of the day and the next scheduled flight, if no more than 72 hours elapse between the inspection and the next scheduled flight. If more than 72 hours elapse between the inspection and the next flight, the inspection must be repeated. This inspection is basically a combination of requirements for checking equipment that requires a daily verification of satisfactory functioning, plus requirements that prescribe searching for and correction of relatively minor problems to prevent their progress to a state that would require major work to remedy. Other items which require inspection at intervals more frequent than prescribed for calendar inspections are also included on the daily inspection and are accomplished along with the daily inspection on the day they become due.

Preflight Inspection

A preflight inspection is performed prior to each flight. This inspection consists of checking the aircraft for flight readiness by performing visual examinations and operational tests to discover defects and maladjustments that, if not corrected, would cause accidents or aborted missions. It also includes a check to determine that the aircraft has been properly serviced for the next flight.

Postflight Inspection

A postflight inspection is performed on aircraft at the termination of the flight. This inspection includes the following:

1. Inspecting critical areas of the aircraft for obvious damage.
2. Servicing the aircraft with fuel, oil, oxygen, etc., to help maintain the aircraft in a ready-for-flight condition.
3. Installing of safety devices such as ejection seats and canopy safety pins, landing gear safety pins, and jury struts to maintain the aircraft in a safe condition.
4. Securing the aircraft after the last flight of the day. This includes installing all protective covers and plugs such as intake and exhaust covers, refrigeration and pressurization plugs, pitot covers, static vent plugs, etc.

NOTE: This inspection is no longer accomplished except where locally authorized to satisfy specific requirements.

Calendar Inspection

The calendar inspection is a thorough and searching inspection of the aircraft. It consists of visual and operational checks of sufficient depth to uncover discrepancies or progressive deterioration within the aircraft that could affect safety of mission accomplishment. This type of inspection is divided into two categories–an ODD calendar and an EVEN calendar inspection–and consists of basic requirements plus additional items scheduled for compliance at less frequent intervals.

Most of the items to be inspected at less frequent intervals are divided evenly so that approximately half of the items are checked on the first (ODD) calendar inspection and the remainder are checked at the second (EVEN) inspection. Subsequent inspections repeat the same ODD–EVEN cycle.

Under this system, the appropriate inspection is conducted at the expiration of a specified number of calendar weeks. Figure 2-4 illustrates a squadron inspection interval.

13154

Figure 2-4.–Squadron inspection interval.

The Calendar Inspection System is an efficient system from a maintenance management standpoint. When aircraft are inspected under this system, the workload planning operation is simplified and the schedule maintenance in process is automatically stabilized.

The first inspection interval subsequent to Navy acceptance of a new aircraft under this inspection system commences on the date or at the time of the acceptance test flight. The first calendar inspection is performed at the completion of this first interval with subsequent inspections performed in sequence as previously mentioned.

The first inspection interval subsequent to standard rework commences on the date entered in the Aircraft Logbook by the rework activity certifying accomplishment of the equivalent calendar inspection. The next calendar inspection due is performed at the completion of this first interval and subsequent inspections are in sequence.

During special rework, the rework activity accomplishes all inspections falling due while the aircraft is in custody of the rework activity. Calendar inspections subsequent to special rework, therefore, continue in sequence. All calendar inspections accomplished by rework are noted in the Aircraft Logbook and the Aeronautical Equipment Service Record.

Acceptance Inspection

A minimum acceptance inspection consists of an inventory of installed material and loose gear, configuration verification, functional test of appropriate emergency systems, and a thorough daily inspection. Accepting activities may elect to increase the depth of inspection if the aircraft conditions warrant.

Conditional Inspection

A conditional inspection is an inspection which does not have a prescribed interval and depends upon certain circumstances or conditions (i.e., hard landings, engine overspeed/overtemp, one time inspections directed by higher authority but not issued as a technical directive).

13155
13154

Maintenance requirements for every model aircraft are promulgated by the Naval Air Systems Command. With every activity using the inspection criteria prescribed for their assigned aircraft models, it follows that any given aircraft model is subject to a standardized program of periodic maintenance wherever it is being operated.

Standardization of planned maintenance procedures is accomplished by use of a Periodic Maintenance Requirements Manual (PMRM), various sets of Maintenance Requirements Cards (MRC's), Sequence Control Charts, and related forms and reports. These publications and forms and their uses are described in the following sections.

PERIODIC MAINTENANCE REQUIREMENTS MANUAL

The Periodic Maintenance Requirements Manual contains all the planned periodic maintenance requirements for the applicable aircraft model for its entire anticipated service life. The maintenance requirements contained in the manual are set forth in a manner to specify the equipment to be inspected or examined and the condition to be sought in each case. Since defects that are discovered during inspections result in unplanned maintenance, and this maintenance cannot be accurately predicted or planned, this type of maintenance requirement is not included in the manual. Maintenance personnel must refer to the proper publications and directives for assembly, disassembly, check, test and repair procedures. The PMRM publication identification code is identical with the other manuals pertaining to the same aircraft model except for part 3. Aircraft manuals are described in chapter 4 of this manual.

Where conflict exists between the information contained in the PMRM and other maintenance directives, the manual–with one exception–takes precedence. This exception is the information given on any Maintenance Requirements Card with a later date than the latest change date given in the PMRM. Although the information given in both these directives should be identical, the cards can be and usually are, changed before the manual.

MAINTENANCE REQUIREMENTS CARDS (MRC'S)

The Maintenance Requirements Cards are the working documents for squadron inspections and preventive maintenance actions. These are 5 x 8 cards arranged by rating and work area to provide the most efficient sequence of accomplishment. Assembled into sets and numbered in sequence, the cards contain pertinent information required by each maintenance man to complete each task. Data for each task includes a description; the time required to perform the task; the power, tool, equipment, and material requirements; and detailed information on such items as adjustments, pressures, and torque values. Also, included, when necessary, is a diagram of the specific area of the aircraft in which the work is to be performed.

Individual sets of MRC's are parepared for preflight, postflight, daily, and calendar inspections. For aircraft models having odd and even calendar intervals, the calendar MRC set is further divided into three groups–calendar, odd calendar, and even calendar. The calendar group contains requirements that must be checked at every calendar inspection, while the other two groups are used alternately with the calendar MRC's. Therefore, at each calendar inspection, two, and only two, of the foregoing groups in the calendar set are used.

The work plan, or order of performing the requirements, specified on the Maintenance Requirements Cards is prearranged in two manners. The preflight, postflight, and daily work is performed item by item in sequential order arranged on consecutively numbered cards. The calendar inspection work is controlled by the order of arrangement of the items on the MRC's and, in addition, employs a sequence chart for scheduling of the MRC's. The calendar MRC's are not necessarily scheduled in numerical card number sequence.

NOTE: No part of any scheduled maintenance is certified (signed off) on the Maintenance Requirements Cards. Therefore, the MRC's may be used as many times as their condition permits.

13156

SEQUENCE CONTROL CHARTS

Sequence Control Charts (SCC's) are used as a guide for the preparation of the actual calendar maintenance work schedule and as a means of controlling the assignment of work and personnel. These charts indicate what MRC's are to be complied with, the number and speciality of the personnel required, the times during which the separate jobs are scheduled to be performed, and the electric and hydraulic power conditions ("power on" or "power off") required during the work.

The SCC's are planned so as to effectively integrate all periodic maintenance work in a manner which will reduce the total out-of-service time required for the complete periodic maintenance job. The SCC's may consist of one, two, or three sheets, according to the requirements of the aircraft model. Generally, small aircraft not requiring engine removal during the calendar inspection will have only one chart containing both airframe and engine requirements to be accomplished on each calendar inspection. If engine removal is required for accomplishment of the calendar inspection, an engine SCC is provided for use by the shop performing the engine inspection.

Three charts are provided for aircraft models having inspection requirements divided between odd and even calendar intervals and requiring engine removal for inspection by shop personnel.

Calendar Sequence Control Charts have no application to the preflight, postflight, daily, or progressive aircraft rework requirements.

A plastic cover is placed over the chart when in use to facilitate marking of progress by the supervisor. The chart and the plastic cover are therefore reusable for as long as their condition warrants.

A portable workstand is used by the calendar maintenance supervisor to provide a local work control center for the accomplishment of calendar maintenance. This stand consists of four stowable legs, a deck tiedown assembly, a plastic chart holder, and a partitioned carrying case for MRC control and storage. A center storage section is provided for reference maintenance manuals. This stand, with the Sequence Control Charts, becomes the control center for the entire calendar inspection.

MAINTENANCE RECORD FORMS

Maintenance record forms are used to enable aircraft maintenance activities to schedule daily maintenance requirements, assign work in a preplanned manner, establish responsibility for work performed, record component replacement and discrepancies discovered, as well as the corrective action taken. The following sections describe the forms provided.

Daily Schedule Maintenance Planning Record

The Daily Schedule Maintenance Planning Record is used to plan and project the daily scheduled maintenance requirements for each individual aircraft between calendar periodic maintenance periods. It aids in assuring that required maintenance is scheduled on time and enables supervisory personnel to plan workloads accordingly. The form provides a number of spaces for each day in which to enter MRC numbers that require compliance on a basis other than every day (7 days, 14 days, conditional, etc.) It also provides a means for writing in all other scheduled maintenance due during the calendar maintenance period designated for the aircraft. This form is filled out to cover the calendar period. This is accomplished while the aircraft is undergoing calendar periodic maintenance so that all scheduled maintenance for the subsequent operating period is known at the time the aircraft is returned to an operational status.

Preflight/Daily/In-Flight Maintenance Record

This record form is used in conjunction with the Daily Schedule Maintenance Planning Record to enable scheduled work to be assigned in a preplanned manner between calendar inspections. This form controls and assigns responsibility for preflight, postflight, and daily scheduled maintenance including the special and conditional work that may be required. These forms can be prepared daily or made up in numbers sufficient to cover a desired period of time. Local conditions provide the best indication of the method to be employed.

13157

INSPECTION PROCEDURES

Under the direction of the activity maintenance officer, Maintenance Control holds a planning conference several days in advance of the calendar inspection due date with representatives of Quality Assurance, Material Control, Production Divisions, designated calendar maintenance supervisor (CMS), and key members of the forthcoming calendar inspection team.

The purpose of the conference is to prepare the SCC by adding on any existing additional requirements. Representative items added on at this time are recent local or command maintenance items, discrepancies, component replacements, change incorporations, and other like items which either cannot be anticipated or cannot be programmed into all inspections on a fixed basis.

After the preinspection planning conference, the marked copy of the SCC is forwarded to quality assurance whose personnel certify that local inspection procedures are incorporated and that necessary MRC's, publications, and required maintenance personnel are available and alerted. The SCC is then forwarded to the CMS who prepares the forms required for the inspection.

To initiate the calendar inspection, the supervisor issues MRC's, in the sequence prescribed by the Sequence Control Chart, to personnel of each rating who make up the inspection crew. A single copy Maintenance Action Form (discussed later in this chapter) is issued to inspection crew personnel each time a segment of the card set is issued for accomplishment. When the inspection or servicing requirements specified on the cards are fulfilled, the Maintenance Action Form (MAF) is completed by the person accomplishing the work or his crew leader and returned with the MRC's to the supervisor. Figure 2-5 illustrates the cycle of paperwork for MAF's and MRC's from the supervisor to the worker and back again.

The supervisor marks the SCC to indicate which MRC's have been issued. Return of completed cards to the supervisor is also reflected on the chart. Even though the workstand provides a physical accounting, by separation, of the completed and uncompleted MRC's, the supervisor doublechecks the return of each MRC by noting it on the chart. A mark should exist on the chart for each completed card, each card not in possession of the supervisor, and each card that could not be completed due to NORS (not operational ready-supply.)

Accomplishment and completion of each issued MRC are the responsibility of the appropriate specialist of the inspection crew. Each card must be completed by the specialist and returned to the supervisor. Uncompleted MRC's are returned to the supervisor and the Maintenance Action Form must contain entries listing the number of cards and items completed, and a notation in detail of which items were not completed and why.

The control of the status and the scheduling of the calendar inspection are the responsibility of the supervisor. It is essential that all discrepancies that are discovered are cleared through him. The supervisor (CMS) notifies the appropriate work centers for the correction of discrepancies which cannot be corrected by the calendar maintenance crew.

A set of Preflight, Postlight, and Daily Maintenance Requirements Cards is maintained in the line shack for each aircraft assigned. Prior to each flight, those preflight, postflight, and daily checks, as required, are performed by the applicable personnel and signed off on the appropriate card.

The Preflight/Daily/In-Flight Maintenance Record (fig. 2-6) should be filled in completely. Inasmuch as several inspections may be in progress at the same time, it becomes especially important that the BUNO and MODEX (or side number) spaces be accurately filled in. In some cases these records may be locally preprinted with the necessary basic information (applicable card number and rating), and the person performing the work need only complete the necessary spaces in longhand. Figure 2-6 illustrates this case.

Daily inspections are accomplished in the same manner as the preflight inspections. The accomplishment of the items on the daily inspection cards is also reported on the Preflight/Daily/In-Flight Maintenance Record. The daily inspection card sets contain the minimum daily, and conditional maintenance requirements for the applicable aircraft. Those card requirements that are to be performed on every daily inspection are titled "Daily." Those card requirements that are titled "Conditional" are

13158

AT.5

Figure 2-5.–Normal MAF and MRC cycle.

items required on other than daily basis; for example, 72 hours, 7 days, 10 days, 30 days, etc. Whenever these special or conditional items are to be included in the daily inspection, the appropriate cards are issued to the persons concerned as part of the daily card set.

FORMS, RECORDS, AND REPORTS

In order that all commands and offices concerned with naval aviation be kept fully informed of the operational and maintenance experiences of naval aviation operating activities, a large variety of records must be maintained and many reports made. Some of the reports provide purely historical information, some furnish statistical data for analyzing efficiency and economy of maintenance and operation, and others have a bearing on the supply support furnished the activity. These records and reports are not limited to aircraft. Support equipment, manhours, and personnel training are representative of other areas of recordkeeping and reporting.

Figure 2-6.–Preflight/Daily/In-flight Maintenance Record.

Through analyses of the data provided, the commands and offices, for whose use the records and reports are submitted, are enabled to better control overall operations. Standardization of maintenance and material areas is improved, unsafe or uneconomical trends are spotted and corrected earlier, and through feedback information, the service experience of other similar activities is made available to all who would find it helpful.

For each record that has to be kept and for every report that has to be made a governing instruction has been issued. These instructions usually give detailed instructions for the preparation of the record or report, prescribe the form and frequency of submission, and indicate the office to which they are to be forwarded. For purely local records such as training records, local instructions are provided to guide the recordkeeping.

The remaining portion of this chapter is devoted to a discussion of a few of the records and reports which are of main concern to the technician.

MAINTENANCE INSTRUCTIONS

Certain basic forms and procedures are set forth in NavAir Instruction 4700.2 (Series) as guidelines for the standardization of maintenance practices. It is essential that each maintenance man become familiar with the purposes and applications of these forms.

When the occasion arises for the aircraft maintenance officer to pass technical information to the mechanics and technicians, a Maintenance Instruction (Form NavAir 4710/7) is issued. This instruction is used for interpreting, amplifying, or clarifying technical directives and maintenance directives received from higher authority. It is also used to promulgate local instructions as necessary.

The instruction is normally prepared by the cognizant division, but it may be prepared by any division designated by the maintenance officer. The rough draft should be reviewed by the quality assurance officer and by the maintenance/material control officer before being submitted to the aircraft maintenance officer for approval.

The Maintenance Instruction (fig.2-7) must be prepared carefully, since this is the instrument by which the division officer directs his men. Command directives received in the form of messages are often so brief that they require considerable amplification and background information in order to be understandable at the working level. On the other hand, directives received in letter form may have been prepared for all aviation activities, and may be excessively lengthy and detailed. Only parts of such directives may apply locally, so they need condensation and selection to adapt them to local conditions.

The same form is used to promulgate instruction of three types: (1) Single Action Main-

INSTRUCTIONS

Check appropriate box for Technical Information, Single Action or Continuing Action Maintenance Instruction.

Enter name of the squadron or activity preparing Instruction.

Enter date Instruction is prepared.

Enter number for identification and filing purposes. Separate sets of annual consecutive numbers shall be established for Technical Information, Single Action and Continuing Action Maintenance Instructions.

Enter brief, accurate description of the general action required.

Enter identification number and title of the directive that is the basis for this Instruction.

Enter models of aircraft or nomenclature of equipment affected.

Enter a complete, concise set of instructions for the performance of the action required. If the instructions are lengthy and involved, reference may be made to the requiring directive for information, in which case it must be attached to and made a part of the Instruction.

Enter when the specified action is to be taken; in what situation; following what occurrence; in connection with what other work; or a calendar deadline, as appropriate.

Identify material required to comply with this Instruction by part number and nomenclature.

If material must be ordered, enter the requisition number. If material request is not necessary, so indicate.

Enter division or divisions responsible for performance of the required action.

Check appropriate box. If a log book entry is required, a verbatim entry shall be provided for the guidance of the person making the entry. The SAMI or CAMI shall show location in log book of such entry.

Enter signature of the division officer who prepared the Instruction.

Enter signature of the Maintenance Officer or his assistant signifying his approval of the content and preparation of the Instruction.

"BuNo or Serial No." and "Date Completed" columns are used only in the case of Single Action Maintenance Instructions. The former will indicate each individual aircraft or piece of equipment subject to the required action, and the Records and Reports Division will use the latter for entering the date of completion of the action to provide a control for planning and record purposes.

AT.8

13162

tenance Instruction–SAMI, (2) Continuing Action Maintenance Instruction–CAMI, (3) Technical Information Maintenance Instruction–TIMI. A separate numbering sequence is set up for each type. This facilitates file control and serves as a cross-reference on work orders and inspection records. Each supporting work order merely carries the serial number of the Maintenance Instruction, rather than a repetition of the description of the work to be accomplished.

Single Action Maintenance Instruction

When work ordered is such that it will be completed on one aircraft or piece of equipment by carrying out the instructions set forth, and will not require further action at any time or in any situation on that aircraft or piece of equipment, it is properly the subject of a SAMI; for example, an Airframe Change on all bureau numbers of a certain model of aircraft.

Continuing Action Maintenance Instruction

A CAMI is issued when the work ordered may be required to be repeated at intervals on the same aircraft or piece of equipment due to elapsed time or as a result of the peculiarities of some particular piece of equipment.

Technical Information Maintenance Instruction

A TIMI may be prepared when a directive or situation dictates that technical information be promulgated within the activity. When it is necessary to disseminate information, such as techniques and local policy, which does not direct the accomplishment of specific work at defined intervals but which is sustaining in nature, a TIMI may properly be issued; for example, procedures and techniques for aircraft fueling.

WORK REQUEST

NavAir Form 4710/6 (fig.2-8) has been provided for use as a work request form. The work request is originated by a maintenance activity. The supporting activity reviews the request and either approves or disapproves. If the request is approved, a work order is issued and the requesting activity is notified when the work is completed. If the request is disapproved, the reason for disapproval is entered on the work request and it is returned to the originator. Detailed instructions for preparing the work request are printed on the back of the form.

MAINTENANCE DATA COLLECTION FORMS

This section outlines the procedure for documenting maintenance actions and actions taken in support of maintenance. These actions consume manhours or material or both. Therefore, manhour accounting is also discussed as part of maintenance data collection. The forms used to record this maintenance data are known as source documents. These source documents furnish the input information for the Maintenance Data Collection System. Each source document provided is used for recording and reporting specific maintenance information and much of this information is recorded in code form. The selection of which form to use depends on the type of work to be accomplished.

The forms selected for discussion are listed as follows:

1. Maintenance Action Form (MAF)–used to record actual maintenance actions (work).
2. Support Action Form (SAF)–a record of tasks performed in support of maintenance.
3. Manhour Accounting Form–a record of manhours expended is essential if efficiency is to be maintained.
4. Technical Directives Compliance Form–used to record actions taken in compliance with technical directives.
5. Configuration Control Form–a record of the configuration of repairable items as a result of compliance with a technical directive.
6. Unsatisfactory Material/Condition Report (UR)–used to report specific information concerning material failure and/or defects and other special situations.

Of the six forms listed, the MAF, SAF, and Manhour Accounting Card are discussed in detail because of the frequency with which the worker comes into contact with them. The remaining forms are described only briefly.

13163

Barley Yellow Dwarf

By Ivan J. Shields
Extension Plant Pathologist

Yellow dwarf, a virus disease of barley and other small grains, has caused reduction of grain yields in many parts of Arizona. This disease, first reported in Arizona in 1953, has been in evidence each growing season since that time. In 1954 and 1956, yellow dwarf caused serious damage to barley and oats grown at lower elevations.

FIGURE 1

FIELD SYMPTOMS

A barley field, infested with yellow dwarf will show very uneven growth (Figure 1). This is because more stunting takes place in plants infected in early stages of growth.

In the seedling stage, leaves will yellow at the tips 12 to 15 days after they are infected. The yellowing progresses downward along the blade; the leaf margins yellowing earlier than the center portions. In some cases yellow blotches develop followed by the entire leaf blade turning a golden to orange yellow. In addition to yellowing an extreme stunting occurs. Tillering may be stimulated, but no heads and hence no seeds are produced.

If infection takes place in later stages, only the uppermost leaves will turn a golden yellow (see arrows, Figure 2). Some heading occurs but the grain is light in weight. Yields may be reduced 50 percent to 60 percent. If the plant reaches the boot stage, before infestation, only the flag leaf will turn a bright yellow following an infection, and the yield will only be slightly reduced.

FIGURE 2

HOW IS IT SPREAD?

Yellow dwarf is transmitted from diseased to healthy plants by several grain-infesting aphids. In Arizona, the corn leaf aphid, the English grain aphid, the apple-grain aphid, and the grass aphid are active vectors of this disease.

During the winter growing season these aphids carry the virus from wild grasses along ditch banks and fence rows into the barley. An infective aphid may infest many plants. Later generations become carriers by feeding first on infected barley and then spreading it to neighboring plants.

HOW IS IT CONTROLLED?

No positive controls are known. The following suggestions should decrease losses.

1. Plant barley to avoid heavy aphid populations during the seedling stage. Barley planted before October 15 or after February 15 usually suffers the greatest losses from yellow dwarf. Aphid populations are usually higher in early fall and late spring.

46164

MAINTENANCE ACTION FORM (MAF)

There are two maintenance action forms, but the format of both is identical. (See fig. 2-9.) The difference is that one is a multiplecopy form and the other is a single copy form. Whether the worker uses the single copy or the multiple copy depends upon whether a repairable item is removed from the aircraft.

A single copy MAF (blue) is used to document the following actions:

1. Repair work on the equipment which does not involve removal of defective or suspected defective repairable components.
2. That portion of calendar, conditional, periodic, acceptance, and transfer inspections which involve the search for (not repair of) defects, sometimes called the "look phase."
3. Removal of components for check, test, inspect, and service actions.
4. Item removal and replacement for cannibalization.
5. Fix-in-place actions discovered during inspections.
6. Recording manhours accumulated during work stoppage for parts or maintenance.
7. Recording accumulated maintenance manhours at the end of a reporting period for a job not completed.
8. To report assistance from work centers in support of a basic work center.
9. In support of a repairable item processing through an Intermediate maintenance activity.

The multiple copy MAF is a set (original and three copies) which is used when processing a defective or suspected defective repairable component through the Intermediate maintenance activity. It is also used to induct a component (including engines) into an Intermediate maintenance activity for compliance with technical directives. However, the multicopy MAF is not used for the accomplishment of test, inspect, and service actions. Instead, see 9, under single copy MAF.

Each copy of the multicopy MAF is used as follows:

Copy 1 (white)–Used for removal/replacement of repairable components from aircraft, engines, or support equipment.

Copy 2 (yellow)–Used to provide status control and suspense information to the Component Control Section of the Supply Support Center for items undergoing processing in the Intermediate maintenance activity.

Copy 3 (green)–Used to document the action taken by the Intermediate maintenance activity on repairable components. Such actions include a determination that the part was beyond the capability of maintenance (BCM), repaired, checked O.K., etc.

Copy 4 (hard back)–Used to provide status control to the component control section of the Supply Support Center and serves as an information copy for all off-station shipment of material requiring rework.

The maintenance action form is originated in the work center. When the work center supervisor is notified of required work, he enters this information in a work center register and assigns men to the job. Upon completion of the work the worker or crew leader fills out the MAF, using information from the supervisor's work center register and verifies completion of the work, manhours expended, materials used, etc. Referring to figure 2-9, completion of the numbered and lettered spaces is as described in the following paragraphs.

Job Control Number (JCN). The job control number is a 10- or 11-character "number" that serves as a base for maintenance data reporting and maintenance control procedures. The JCN provides separate identification of each maintenance action, when necessary. It also identifies the maintenance actions accomplished by Intermediate maintenance activities in support of organizations or an organizational discrepancy. The four parts of the JCN are organization code, date code, sequence number, and suffix and are thus explained.

The organization code is a 3-character code composed of letters and numerals (alphanumeric) which identifies an organization. This part of the JCN is published by higher authority for each individual activity performing or responsible for aircraft maintenance and always remains constant within the activity.

The date code identifies the date of which the JCN was initiated or assigned to a job. Therefore, this is not necessarily the date on which the work was actually started. NOTE: The date code, known as the Julian date, identifies the year and the numerical day of the year and consists of four numbers. The first number indi-

Figure 2-9.–Maintenance action form (MAF).

V313166

cates the last digit of the calendar year, the next three numbers specify the number of days in the calendar year which have elapsed since January 1 of that year; for example, the Julian date 8350 identifies the 350th day of 1968 or, in more familiar terms, 15 December 1968; 9006 is the 6th day of 1969 or January 6, 1969. All dates used in the maintenance data reporting program are reported in Julian dates since any date in any 10-year period can be shown in just four digits. Encoding the date in this manner simplifies recordkeeping the data reduction by machine methods.

The sequence number part of the JCN (identified SER on the form) is either a 3-digit number that runs consecutively from 001 to 999 or a 3-character alphanumeric code with an alphabetic first character and two numbers which run from 00 to 99. The sequence number is normally assigned in sequence as new jobs come up. When the number 999 (or alphanumerically, 99) has been assigned, the next number in sequence is again 001. The alphanumerical sequence numbers are used only when documenting calendar inspection maintenance actions.

The JCN suffix is a single alphabetic character which is added to the basic JCN (those parts just discussed) to identify a subcomponent repair job which was done separately from the major repair job. This code applies to Intermediate maintenance only. An example of this is when a defective item is replaced with a good one during the course of a major job. The MAF job control number used to process the removed part through repair (Intermediate) maintenance would be the same basic code as the major job but the suffix A would be added to identify the subcomponent repair.

Type Equipment. The type equipment code is a 4-character code consisting entirely of letters. The type equipment code on the MAF shown in figure 2-9 is the code for the S-2A aircraft. These codes are listed in official directives and are mandatory for use.

Bu/Ser No. A bureau number or serial number is a number that identifies a specific end item or component, including aircraft and their components. The number is usually assigned by the manufacturer (serial numbers) or the Navy (bureau numbers), and is used to differentiate between a given end item and others of the same type, model, series, design, etc.

Action Org. Entered here is the organization code number of the organization performing the work. In case the same organization that assigned the JCN is performing the work, the code entered is the same as the organization code in the JCN.

Work Center. Entered here is the work center code of the work center accomplishing the maintenance action described on the MAF. This is either (1) the code of the worker's assigned work center, or (2) if temporarily assigned, the code of the work center to which he is temporarily assigned.

Maintenance Level. Entered here is a checkmark in the block which describes the level of maintenance being performed. This information should not be confused with organizational assignment of personnel. For instance, a man assigned to an Intermediate maintenance activity may actually work on an aircraft. Such a job would normally be considered as Organizational level work. As a general rule, all work performed on aircraft or missiles is considered as Organizational level maintenance and work performed off the aircraft or missile as Intermediate level maintenance.

Action Date. Entered here is the Julian date on which (1) the action is completed, or (2) the MAF is turned in to account for manhours accumulated against a job, or (3) the job is turned over to another work center, or (4) a job is interrupted due to the fact that supply must go off station for parts, or (5) a reporting period ends.

Work Unit. The work unit code is usually a 5- or 7-character alphanumeric code which normally identifies the system, subsystem, component and part of the item being worked on. (The look phase of calendar inspections is documented on single copy MAF's by entering "030" in block 8, "0" in blocks 9 and 11, and "000" in block 12.) Work unit codes are published in Work Unit Code Manuals for end items in two major categories; Type/model/series for aircraft, drones, and missiles; and aircraft maintenance support equipment. Five-character work unit codes from these manuals are used to code all work on an end item and its components. The sixth and seventh characters are used in benchwork (off equipment) to allow identification of repairable subassemblies of major components.

ว๋ว๋ว๋ว๋67

When Discd. When discovered codes are single alphabetic characters which identify when the need for maintenance was discovered. These codes are applicable to the MAF only. There are two sets of when discovered codes, covering the following equipment categories: Aircraft and engines and aircraft maintenance support equipment.

When discovered codes relate primarily to conditions under which the malfunction or discrepancy was discovered rather than to the time in days or hours. For instance, code F (aircraft and engines) identifies a discrepancy or other need for maintenance that was discovered during the pilot's weekly inspection, while code F (aircraft maintenance support equipment) indicates that a need for additional maintenance was discovered during a period of unscheduled maintenance on the support equipment.

Type Maint. The type maintenance code is 1-character alphabetic code used to describe the type of work being accomplished (i.e., scheduled, unscheduled, supply support, etc.). Definitions and explanations of all these codes are contained in an appendix to the Standard Navy Maintenance and Material Management Program Manual.

Action Taken. The action taken code is a 1-character alphabetic or numeric code which describes the action that has been taken to correct the discrepancy. The action taken code "A" (Discrepancy Checked, No Repair Required) is used only in those cases where an inspection or operational check has been performed and the reported trouble cannot be duplicated or does not exist. In these cases the malfunction description code is "799" (No Defect) rather than a code that describes the reported discrepancy.

MAL. (Malfunction Description). The malfunction description code is a 3-character numeric code used to describe the malfunction occurring on or in the item identified by the work unit code on the maintenance data reporting forms. These codes are listed in alphabetical and numerical sequence in all Work Unit Code Manuals.

Items Proc. (Items Processed). Items processed, for the purposes of maintenance data reporting, is defined as the number of times that an action indicated by an action taken code is applied to the item identified by the work unit code recorded on an MDR form, or the number of times a support action is accomplished. EXAMPLE: Since the fuel nozzle of a jet engine is a coded item, replacement of five fuel nozzles would be documented as five items processed. In contrast to this, replacement of several tubes in an electronic assembly would be documented as one item processed with the work unit code identifying the electronic assembly being repaired, and the action taken code indicating repair.

Manhours. Entries in the manhours block of the MAF's represent all manhours expended by assigned personnel in completion of the work described on the source document. Hours and/or tenths worked multiplied by the number of men working equals total manhours. Time expended in exceptions of three-tenths of an hour or less is included in the total labor hours for the job. Exceptions which exceed three-tenths of an hour are not accounted for on maintenance action forms. These exceptions are charged to the proper labor distribution codes described later in this chapter. Entries in the manhour block of the maintenance data reporting (MDR) forms do not include labor hours for any work center other than the one submitting the document. For example, if two work centers jointly correct a discrepancy (same JCN) on the same aircraft or equipment, workers from each work center submit a source document with that particular work center's labor hours in the manhour block.

EMT. (Elapsed Maintenance Time). Elapsed maintenance time is defined as the actual clock time, in hours and tenths, that maintenance was being performed on a job. Although the EMT is directly related to job manhours, it is not to be confused with total manhours required to complete a job.

Block 16. Left blank. Use of this block is not currently prescribed.

Removed Item. This block will be completed on the four part MAF when a reparable component/part is removed from the equipment on which work is being accomplished. Enter the Reparable Item Code (RIC) and component serial number of the removed item in this block. If a RIC is not assigned, enter the manufacturer's code, serial number, part number (if more than fifteen (15) characters enter the last 15), and the meter reading to the nearest whole number. All

ea/13168

meter readings will be prefixed with the letter "M." If no meter is installed, enter the time since new on the type equipment identified in block two (2) of the MAF.

Installed Item. Enter the Reparable Item Code (RIC) and component serial number of the installed item in this block. If a RIC is not assigned, enter the manufacturer's code, serial number, and part number (if more than fifteen (15) characters enter the last (15) of the installed item). Enter the meter readings in block 21.4 (blank block following the part number). All meter readings will be prefixed with the letter "M." If no meter is installed, enter the time since new on the type equipment identified in block two (2) of the MAF.

NOTE: The Removed/Installed item blocks on the single copy MAF shall be completed when recording cannibalization actions, and when reparable items are removed or re-installed to facilitate other maintenance and recorded as separate maintenance actions. No entries will be made in these blocks on the single copy MAF when the Action Taken Code is L, M, N, S, or when removing items for test, inspection, or service and their subsequent installation.

Discrepancy. A narrative description of the reported discrepancy or work to be performed is entered in this space. The appropriate arrow below the word DISCREPANCY is circled to indicate the flying status of the aircraft.

Corrective Action. A narrative description of the work accomplished in compliance with the discrepancy block is entered here by the person accomplishing the job.

Entries Required. Applicable checkmarks in the entries required space are made when the action or discrepancy requires logbook or accessory record card entries. Maintenance control enters a checkmark in the configuration block when configuration of the equipment is affected. The person making the entries signs his name and rate in the adjacent signature block.

Corrected By. The worker or crewleader who accomplishes or supervises the repair signs his name and rate in this block.

Inspected By. The Quality Assurance Representative or Collateral Duty inspector who inspects the job for proper standards signs his name and rate in this block.

Supervisor. The work center supervisor or his assistant signs his name and rate in this block to indicate that screening and other appropriate action has been accomplished.

Repair Cycle Data. Enter the Julian dates for the following: 1. Removed; 2. Received material control; 3. Work started; and 4. Completed. Check the appropriate block to indicate if the item is ready for issue (RFI), requires rework (B COND), or is recommended for survey or salvage (R/S).

During the actual repair, if the job is interrupted for one or more days due to a lack of parts, enter the Julian date that the job goes AWP (Awaiting Parts) adjacent to block 5 or 7. Enter the Julian date that the parts are received adjacent to block 6 or 8. Blocks 5 and 6 are used the first time the job status is AWP and blocks 7 and 8 are used the second time the status is AWP. If the job status is AWP more than twice, dummy dates within the actual repair time are entered adjacent to blocks 7 and 8 to reflect the actual number of days lost due to the second and subsequent AWP status.

Failed Material. On the single copy MAF, enter the action taken code, malfunction description code, quantity, manufacturer's code, and part number of failed material in this block if the parts replaced during repair are parts, bits, and pieces that have failed in a major component. If the failed item is removed and replaced, enter action taken code "R" (removed and replaced). If the removed item is removed, repaired, and reinstalled, at the Organizational level of maintenance, enter action taken code "C" (repaired). It is intended that this block be utilized to record only primary items that have failed. It is not intended to be used for recording all items replaced (i.e., common hardware, nuts, screws, safety wire, etc.), nor is it to be used to record routine replacement of seals, gaskets, washers, fittings, etc., that are installed during overhaul or repair.

Accumulated Hours. The work centers use this block to record manhours and elapsed maintenance time (EMT) accumulated against a job. Whenever (1) completing a repair action, (2) turning in a supplementing document in support of the job, (3) making a work center change, (4) a reporting period ends, or (5) going

89 1831 69

AWP, manhours and EMT are totaled in this section and entered in blocks 14 and 15 (near the top of the MAF) of the submitted document, after which the entries in the accumulated hours block are lined through to indicate they have already been documented.

Required Material. Whenever material is required to complete a maintenance action, it is requisitioned. In this section a line for each item ordered is filled in. Entered are the requisition number, manufacturer's code, part number, quantity, priority, date and time the material was ordered, and the date and time the material was received.

SUPPORT ACTION FORM (SAF)

The separate reporting of support type data is designed so that time expended in the accomplishment of repetitious type tasks that consume many manhours (but do not involve malfunctions, repairs, or condemnation action) may be easily identified, reported, and monitored. Manhours expended in support duties (such as aircraft refueling, engine or tire buildup, parachute packing, etc.) are documented on the support action form (SAF).

The SAF is a standard electric accounting machine (EAM) card which may be either handscribed or prepunched and preprinted, depending upon the desires and requirements of local maintenance managers. In either case, all support action forms are signed by the work center supervisor to indicate that screening has been accomplished. Figure 2-10 illustrates a handscribed support action form.

In order to identify manhours expended in specific categories of support type work, 3-character codes known as support action codes are used. Nine basic categories of support type work and the related code for each are listed on the back of the SAF form together with type maintenance codes.

Support codes may be further broken down within basic categories if deemed appropriate by local command; i.e., 011, 012, etc. In the event such a breakdown is desired, its use is controlled by the maintenance officer and managed by the analysis section. The areas of support work covered by each basic category are defined in detail in an appendix to the Maintenance and Material Management Manual (3M Manual).

Support action forms are filled out in the following manner:

Type Equipment Code. Enter a 4-character code that identifies the equipment on which support work is being accomplished; i.e., aircraft, engines, ground support equipment, etc. This code is found in appendix H of the 3-M Manual.

Action Organization. If the SAF is not preprinted and prepunched, enter the 3-character code that identifies the organization accomplishing the support action. This is the same alphanumeric organization code that was explained in connection with the maintenance action form.

Work Center Code. This, too, is the same numeric code series that is used with the MAF.

Maintenance Level. If the card is not prepunched and preprinted, enter the 1-character numeric code that identifies the maintenance level of the support action being performed. These codes are provided on the front of the SAF.

Action Date. The action date is the Julian date of the day the support action was completed.

Support Code. Enter the 3-character numeric code that identifies the category of work in which the support action was accomplished. These codes are listed on the back of the SAF.

Type Maintenance Code. This is a 1-character alphabetic code that identified the type of support maintenance that was accomplished.

Items Processed. Entered here is the number of items processed, or the number of times that the support action identified in the support code block has been accomplished (i.e., 4 aircraft refueled, 3 preflight inspections accomplished, etc.).

Manhours. Enter the total number of manhours (in hours and tenths of hours) spent in the accomplishment of the support action documented on the same line of the card. A maximum of 999.9 manhours may be reported on one line entry.

Local Control. Provided for local use, if desired.

Signature. Enter the signature of the person documenting the support action.

Replenish. If preprinted, prepunched cards are used, enter a checkmark in the REPL block when more cards are needed. The maintenance officer controls and analysis section coordinates the production, volume, and distribution of preprinted prepunched cards.

Figure 2-10.–Support action form (SAF).

The support action form is designed so that documentation may be completed by either the work center supervisor or the individual worker. Additionally, the card provides a multiple entry feature so that several different entries may be made on the same form.

MANHOUR ACCOUNTING AND FORMS

The effective use of available manpower is an important function of maintenance management. Manhour accounting is an important part of the maintenance data collection system. The purpose of collecting manhour data is to provide management with essential information necessary to plan and direct more efficiently the distribution of assigned personnel.

The Manhour Accounting System is based upon the "exception" principle; that is, only the deviations or exceptions from normal are reported. Through the use of master rosters, electric accounting machine cards, and machine processed reports, the system provides sum-

13171

maries of the hours expended by maintenance personnel during the normal working day or in an overtime status. Basically, the system is designed so that the normal working hours for each person assigned to the maintenance activity are allotted or assigned to work centers by types of labor at the beginning of each reporting period. Exceptions from these normal working hours, or labor types, are reported by use of manhour accounting cards. Data processing machines add or subtract the exceptions reported on the manhour accounting cards from the initial manhour allotment. These exceptions and the working hours allotted at the beginning of the period serve as the basis for the daily and monthly manhour accounting reports mentioned in the foregoing. These reports are forwarded to the maintenance officers and supervisors for validation and utilization. Each supervisor and worker must thoroughly understand the importance of the system, its operation, and the need for continual accuracy. Detailed instructions pertinent to the content and use of manhour accounting reports are contained in the following paragraphs.

At the beginning of each reporting period, generally the first of the calendar month, manhours are assigned to every work center to which personnel are assigned. These manhours are based on an 8-hour work day 5 days per week for every person assigned. Not included in these (original assigned manhours) are any hours for work on Saturdays, Sundays, or holidays during the month. If every person assigned to the work center could be continuously employed throughout the month during all the time available for work, there would be no need for manhour reporting, as the time would be accounted for on the maintenance action form. Since continuous employment is not possible, each worker must report what he did when he was not working during any period in excess of 20 minutes, or approximately three-tenths of an hour.

To simplify reporting of hours spent in a labor category other than that for which assigned, a group of prepunched, preprinted manhour accounting cards is provided for every worker assigned. A card is initiated each time a person excepts from normal for a period in excess of three-tenths of an hour and is completed at the end of the exception. The most frequent exceptions requiring the submission of manhour accounting cards are (1) each time a person is assigned to, or transferred from, a work center or organization, (2) each time a person performs work in other than his regularly assigned labor code, (3) each time a person is absent from his work center for nonmaintenance purposes such as watches, leave, sick, special liberty, etc., and (4) each time a person works overtime during a single work day or on his day off (holiday, Sunday, etc.).

Manhour accounting cards are, for the most part, prepunched and preprinted. However, handscribed cards have a place in the system. A handscribed card is illustrated in figure 2-11.

Handscribed manhour accounting cards are normally used to report (1) newly assigned personnel, (2) temporarily assigned personnel, (3) composite manhours involving more than one person, and (4) whenever prepunched, preprinted cards are not available.

The use of the blocks and spaces on the manhour accounting card is discussed in the following paragraphs.

Block 1–Organization Code. The organization code is the same 3-character alphanumeric code described for use with the maintenance action form. Use of the code simplifies the identification of the unit to which a person or persons is/are attached or temporarily assigned. For example, TO1 is the code for NAS, Pensacola, Florida, and is much easier and faster to write in than the name of the activity.

Block 2–Work Center Code. The work center code identifies the functional area to which a person is assigned or temporarily assigned. A standard system of work center codes is prescribed. Therefore, a technician assigned to the avionics division at the Intermediate level of maintenance anywhere in the world will use the same work center code. Those technicians attached to the electronics branch at the organizational level of maintenance all use the same work center code.

Block 3–Name and Initials. This block is self-explanatory, except in the case of composite cards (used for two or more persons) enter the applicable number of men; i.e., "2 men," "4 men,", etc.

Block 4–Grade Code. This code is a 3-character numeric or alphanumeric code used to designate the grade and status of the individual

13172

Figure 2-11.–Manhour accounting card. AT.12

being reported. All military grade codes start with 0 and range upward from 001 (recruit) to 019 (captain/colonel). All civil service codes start with G and correspond to their pay status. For example, a GS-1 code is G01 and the top is G14 for a GS-14. Grade codes C01 through C04 are special civilian codes and are provided for use where necessary as directed by the major command.

Block 5–Labor Code. Labor codes in five major categories are prescribed for use here. Manhour expenditures are charged to the labor code which best describes the type of labor performed or how a worker's time was spent. The five major categories are as follows: Direct Labor (500), Productive Indirect (600), Nonproductive (700), Duty Absence (800), and Nonduty Absence (900). All of these code groups except Direct Labor employ digits other than 00 to more precisely picture what was done. For example, Duty Absence (800) is further divided into Military Duty (810) and Military Training (830).

Block 6–NEC/MOS. In this block is entered the primary Navy Enlisted Classification Code or Marine Corps Military Occupation Specialty Code for newly assigned personnel only. Naval Officer Billet Codes (NOBC) or designators may be used for officers. If desired, a person's rating may be entered in block 6a.

Block 7–Initials. The initials of the work center supervisor are entered here to indicate that screening has been accomplished. Every worker assigned to a work center is responsible for submitting his own cards, except when he is absent at the end of a reporting period. In such cases, the supervisor submits the necessary cards. It is the responsibility of the work center supervisor to see that every card submitted by everyone is correct in every detail.

Block 8–Type of Change. It must be kept in mind that maintenance manhours are not reported on manhour accounting cards. Whenever the normal routine (which is set up on the electric accounting machines) varies or changes for any of the reasons listed in block 8, a card must be submitted AFTER the change occurs. For instance, after being temporarily assigned or transferred or immediately after working overtime. A check (✓) in a block 8 space is nearly always accompanied by an entry in block 9, 10, 11, and/or 12. An exception to this is "Replenishments." A preprinted, prepunched card, checked in the "Replenishments" space, is submitted by the man concerned when the number of preprinted, prepunched cards remaining in his personal stack is less than 10. The data center will forward him a new supply the next day. The relationship of block 8 spaces to blocks 9, 10, 11, and 12 will be discussed in conjunction with the coverage of the latter group of blocks.

Block 9–Transaction Work Center. Block 9 is used in conjunction with the "Temporarily

STIC 13173

2. Use tolerant or resistant varieties when available. The Rojo variety is tolerant to yellow dwarf. In variety trials in the Salt River Valley, Rojo yielded as well as Arivat.

3. Control grasses on borders of fields and along ditch banks to reduce areas for aphid build-up.

4. Aphid control by use of insecticides has not proven effective in stopping the spread of yellow dwarf. Additional aphids move in after insecticide application and build up quickly due to absence of predators.

RESEARCH IN PROGRESS IN ARIZONA

Resistance to yellow dwarf has been found in a number of breeding lines. The resistance from four of these lines is being bred into several high-yielding varieties for Arizona.

Assigned" and "Temporarily Transferred" categories in block 8. When a man is temporarily transferred to another work center, the change requires the initiation of two cards, because it involves two work centers. At his permanent work center he initiates a card checked "Temporarily Transferred" in block 8, and his temporary work center code is entered in block 9. When he arrives at his temporary work center he initiates the second card. On this card, "Temporarily Assigned" is checked in block 8, and the code number for his permanent work center is entered in block 9.

Block 10–Date. Block 10 is not filled in until the temporary work assignment is completed. At that time the Julian date is entered in this block, identifying the day the exception was completed.

Block 11–Hours. Upon completion of the exception, the number of hours and tenths of hours involved in the exception are entered here. Space is provided for 999.9 hours to be reported on a single card. When "Newly Assigned" (block 8) is checked, the number of hours reported is the number of hours of normal working time remaining in the reporting period. If "Temporarily Assigned" is the reason for submitting the card, the total elapsed number of working hours while so assigned is reported. The exception to this is when a temporary assignment extends into the next reporting period. In such cases a temporarily assigned card is submitted at the end of the month with that month's hours reported and, when the exception ends during the next reporting period, another temporarily assigned card is submitted to report only the number of temporarily assigned hours elapsed in that reporting period.

If "Transferred" (block 8) is the reason for submitting a manhour accounting card, the number of working hours remaining in the reporting period is reported. It will be recalled that the total number of working hours available for a reporting period for a work center is obtained by multiplying the number of men assigned by 5 days per week and 8 hours per day. When a person is transferred during the reporting period, all the working hours that he would have worked had he remained must be subtracted from the work center's total manhours available. The same reasoning holds true for "Temporarily Assigned" where the number of hours in this category is added to the temporary work center's totals and "Temporarily Transferred" where the number of hours away is also deducted from the permanent work center's totals.

Block 12–Transaction Code. An entry in this block is mandatory if "Labor Code Change" or "Overtime" has been checked in Block 8. A checkmark is entered to identify the labor code in which manhours were expended. If the "Other" line is checked, the appropriate subcode promulgated by the analysis section is entered in the space provided. The majority of manhour accounting cards submitted are "Labor Code Change."

TECHNICAL DIRECTIVES COMPLIANCE FORM

The Technical Directive Compliance Form (TDCF) is a single page form that is also used to document all technical directive maintenance actions. The TDCF is used by reporting custodians for preplanning workload and material requirements and for configuration accounting. Data obtained from these forms allows identification of all direct manhours expended complying with technical directives.

Unlike the MAF and SAF, the TDCF is originated by maintenance or production control. It is normally initiated upon receipt of each approved applicable technical directive.

There are several factors which must be considered in determining the number of copies required. In all cases, an original and one copy must be originated. If parts or kits are required for compliance, one copy is forwarded to material control. The original is forwarded to the primary work center when required material is available and the directive is scheduled for completion. If more than one work center is involved, one copy is forwarded to each assisting work center. One copy is held in suspense by maintenance control until the completed original is received from the work center.

CONFIGURATION CONTROL FORM

The Configuration Control Form (CCF) is a single page multiple entry document which is used to report the part number change of reparable items as a result of technical directive compliance on an aircraft, engine, or other

13174

selected item of equipment. This form is also used to report the removal and the installation of all items listed on the respective type equipment Configured Item List. A CCF is not required to report the removal and reinstallation of the same part number and serial numbered item on the same equipment when both actions take place as a single maintenance action. The CCF is normally initiated by maintenance control and completed by the primary work center or maintenance control.

NOTE: Configured items are selected items which require configuration status accounting. Items selected normally affect mission capability and can be interchanged with a similar item that results in a different mission capability, or are management attention or time compliance items. Many of the data blocks on the CCF are transcribed directly from the corresponding blocks on the TDCF or the MAF.

UNSATISFACTORY MATERIAL CONDITION REPORT (UR)

The Unsatisfactory Material/Condition Report, hereafter called UR, is a four-part, carbon interleafed, snap-out form. All activities concerned with maintenance of naval aircraft should use the UR's to report SAFETY, URGENT, and SPECIAL SITUATIONS.

The UR provides a system for submittal of specific information concerning failures, material defects, and other critical situations affecting naval aeronautical equipment which require prompt attention and corrective action. The UR is used for special situations as follows:

1. Report hazards to flight safety. The report in such instances serves as a followup to a Flight Safety Message in accordance with NavAir 4700.2 Series Instructions.

2. Report errors or omissions in aircraft and equipment manuals.

3. Report aeronautical equipment found in an unsatisfactory condition as a result of design deficiency, faulty manufacture, faulty overhaul, or faulty preservation and packaging.

4. Make special reports on any weapons system or equipment specifically requested by the Naval Air Systems Command for special reliability studies.

The front page of the UR contains instructions for the completion of the form. Using a typewriter or ball point pen, fill out the required spaces. The second page of the completed form is forwarded to the Naval Technical Services Facility, and the third page is retained by the originating activity for record purposes. The tag copy (fourth page) is attached to the material being turned in to supply or released for investigation. In the event that the material is not turned in to supply or released for investigation, the tag copy is discarded.

VISUAL INFORMATION DISPLAY SYSTEM (VIDS)

The Visual Information Display System (VIDS) is a time charting management tool which provides a graphic display of vital, up-to-date information on a continuing basis. The system correlates all aircraft status information, particularly awaiting parts and flyable discrepancies, and assigns a relative importance to each item. Additionally, the system displays the amount of time required to perform any maintenance and the number of personnel available and engaged in work. The ability to review the overall situation and determine what resources are available enables the maintenance officer and maintenance control officer or supervisor to more effectively and efficiently carry out his duties. This information is displayed on specially configured cardex type display boards.

DISPLAY BOARDS

VIDS boards consist of enlarged cardex type pockets scaled horizontally to represent hourly time periods. Each pocket is overlapped by the one above so that approximately a 3/8-inch strip is visible at the bottom of the pocket. Boards are available in three sizes–100 pocket (40" x 40"), 50 pocket (40" x 26"), 25 pocket (40" x 14"), and in three standard configurations. The configurations are as follows:

1. Organizational, flight maintenance board. This board provides current status of each aircraft plus displaying scheduled/unscheduled maintenance, including outstanding flyable discrepancies, parts on order, scheduled flights, and aircraft configuration. The current and projected workload of each work center and the number of labor code 500 personnel available for work are also displayed on this board.

13175

2. Material control status board. Outstanding material requisitions are displayed on this board by aircraft modex, work center, and document number.

3. Work center board. The work center board displays the work assignments by name in the work center plus providing space for individual technical qualifications record. Space is also provided for pending assignments, not assigned tasks, and those in an AWP (aircraft awaiting parts) status. The top pocket is configured to show the status of special support equipment (SSE) required by the particular work center.

IMPLEMENTATION PROCEDURES

To make the implementation phase as smooth as possible, a thorough indoctrination of the maintenance/material control personnel and work center supervisors is necessary. All problems concerning operating procedures, information flow, and communication procedures should be resolved prior to the implementation date. Certain steps are necessary if the transition is to be made in an orderly manner with minimum disruption of the maintenance effort.

Information Display Requirements

Efficient management of the maintenance effort requires certain information concerning the resources of the activity be available. The range and depth of information requirements are determined by such factors as mission, size, and physical layout of facilities. For purposes of standardization and to insure that the minimum information requirements are displayed, the following guidelines should apply:

1. Maintenance control.
   a. Inventory of aircraft.
   b. Aircraft configuration.
   c. Aircraft airframe / engine / component/time.
   d. Aircraft / equipment discrepancy status.
   e. Work center loading.
   f. Projected flight and maintenance requirements.
2. Material control.
   a. Outstanding requisitions by aircraft and priority.
   b. Outstanding requisitions not identified to a specific aircraft.
   c. Master register listing by supply document number.
3. Work center.
   a. Personnel status.
   b. Training/qualification record.
   c. IN WORK discrepancies and personnel assigned.
   d. AWP and pending discrepancies.

OPERATING PROCEDURES

There are two approved methods of operation for the Organizational Maintenance Control VIDS. Both methods are in consonance with current OpNav directives and are adaptable to any type activity. With either method, the primary consideration is placing maintenance control in CONTROL OF MAINTENANCE.

Time Charting Method

This method is a 3-day projection–title columns with Julian date; i. e., 9060, 9061, and 9062, and continue sequence as workdays progress. At the beginning of each shift, the maintenance control supervisor will verify his status board(s) with the various work centers. Each work center supervisor will inform him of the number of labor code 500 personnel available for work. These numbers will be indicated by the use of manpower indicators on the work center sections of the board.

Each discrepancy will be transcribed on an appropriate colored maintenance control register along with other pertinent information available at that time. Red registers will be used for discrepancies that place the aircraft in a nonflyable status. Blue registers are used for flyable discrepancies that do not place the aircraft in a reduced material condition (RMC), and an orange register for discrepancies that cause the aircraft to be placed in a reduced material condition.

The maintenance control supervisor will determine whether the affected work center(s) has the capability to handle the discrepancy at the present time. In making this decision he should utilize the manpower information displayed on the work center section, the present workload, and priority of the IN WORK and

13176

PENDING discrepancies. Based on his decision, the following procedures will be used.

1. Work center has capability. Maintenance control will transmit pertinent information to the affected work center(s). At this time, the work center supervisor will provide maintenance control with the estimated time of completion (ETC), work unit code, and number of personnel that will be assigned to the task. This information is entered in the appropriate spaces of the register. An Equipment Statistical Data (ESD) card will be initiated to indicate a change in the aircraft condition. The colored tabs at the bottom of the register, in excess of the ETC, are folded under. Copy 1, along with the ESD card, is placed in the aircraft pocket or pockets under the appropriate day and time frames. Copy 2 is placed in the appropriate work center pocket in the same manner, and the "men assigned" sliding tab is adjusted to indicate number of personnel assigned. Copy 3 will be forwarded to Quality Assurance for information purposes.

2. Work center does not have capability at present time. Maintenance control will indicate on the register that the discrepancy is in an AWM (aircraft waiting maintenance) status and will schedule the work at a later date and/or time. Copy 1 will be placed in the aircraft pocket, and copies 2 and 3 in the work center pocket under the appropriate date and time frame. An ESD card will be initiated and placed in the aircraft pocket. When the discrepancy is scheduled IN WORK, procedures described above will be utilized.

The register will remain on the board in an IN WORK status until the discrepancy is completed or unless the aircraft goes AWP or AWM. AWP and AWM status are described as follows:

AWP. The existing ESD card is closed out and a new one initiated to show current status. A black tab is placed in front of the register to provide visual recognition of the AWP status. Copy 2 of the register is moved to the AWP section of the work center board. When material is received, discrepancy is rescheduled for work.

AWM. When maintenance control determines that a work center must go AWM on a discrepancy, the pertinent information will be entered. The discrepancy will be rescheduled at a later date and/or time and register copies 1 and 2 will be moved on the board to the appropriate time frame. These registers can be flagged with an appropriate color for easy identification.

When maintenance control is notified that a discrepancy has been corrected, the registers (copies 1 and 2) will be removed from the board and copy 2 destroyed. Pertinent information will be entered in the appropriate blocks of copy 1.

Copy 1 should be retained in a temporary file until the MDR document passes through maintenance control. At that time, all necessary information is verified and then the register is filed in accordance with existing instructions. Insure that the ESD card reflects the current status of the aircraft.

Current Discrepancy
Status Display Method

This method utilizes three columns–PENDING, IN WORK, and AWP–each encompassing one 24-hour period. At the beginning of each shift, the maintenance control supervisor will verify his status board(s) with the various work centers. The supervisor will then determine which work centers have capability to handle incoming discrepancies. In making this decision, he should utilize the manpower information displayed on the work center section, the present workload, and priority of the IN WORK and PENDING discrepancies. Based on his decision, the following procedures will be used:

1. Work center has capability. Maintenance control will transmit pertinent information to the affected work center(s). At this time, the work center supervisor will provide maintenance control with the estimated time of completion (ETC), work unit code, and number of personnel that will be assigned to the task. This information is entered in the appropriate spaces of the register. An Equipment Statistical Data (ESD) card will be initiated to indicate a change in the aircraft condition. The colored tabs at the bottom of the register, in excess of the ETC, are folded under. Copy 1, along with the ESD card, is placed in the aircraft pocket under the heading IN WORK and time frames. Copy 2 is placed in the appropriate work center pocket in the same manner (column and time frame),

13176
13177

and the "men assigned" sliding tab is adjusted to indicate number of personnel assigned. Copy 3 will be forwarded to Quality Assurance.

2. Work center does not have capability at present time. Maintenance control will indicate on the register that the discrepancy is in an AWM status and will schedule the work at a later date and/or time. Copy 1 will be placed in the aircraft pocket under the heading PENDING. Copies 2 and 3 are placed in the appropriate work center pocket under the same heading.

An ESD card will be initiated and placed in the aircraft pocket. When the discrepancy is scheduled INWORK, procedures described under work center capability will be utilized.

When a discrepancy has been scheduled IN WORK, the register will remain on the board under the heading IN WORK until the discrepancy has been completed or it is necessary to go AWP or AWM.

AWP. When maintenance control determines that a work center must go AWP on a discrepancy, copy 1 is placed in the aircraft pocket under the heading AWP. Copy 2 is placed in the appropriate work center pocket under the same heading. When the material is received, the discrepancy is rescheduled for work. Insure that the ESD card reflects the current status of the aircraft.

AWM. When maintenance control determines that a work center must go AWM on a discrepancy, the pertinent information will be entered in the appropriate block of copy 1. Both copy 1 and the ESD card are then placed in the aircraft pocket under the heading PENDING. Copy 2 is placed in the appropriate work center pocket under the same heading. The discrepancy will be rescheduled at a later date and/or time and the registers (copies 1 and 2) will be moved to the appropriate pockets under the heading IN WORK. Copy 1 will be updated by entering the IN WORK time in the appropriate blocks.

When maintenance control is notified that the discrepancy has been corrected, the registers (copies 1 and 2) will be removed from the board and copy 2 destroyed. Pertinent information will be entered in the appropriate blocks of copy 1.

Copy 1 should be retained in a temporary file until the source document is received in maintenance control. At that time, all necessary information is verified and then the register is filed in accordance with existing instructions. Insure that the ESD card reflects current status of the aircraft.

Maintenance Control Information

The number of the assisting work center(s) is written in the appropriate block when a discrepancy is transcribed on a maintenance control register. A copy 2 register of the same color as the primary register is made out for each assisting work center and placed in the appropriate work center section. As each assisting work center completes their portion of the discrepancy, the source document that is submitted will be verified with the copy 1 register and that particular work center will be crossed out. The initials of the person calling in the completion will be written above the work center number.

ESD cards can be placed on the VIDS board by either placing the card behind copy 1 of the register or inserting the card in the pocket on the extreme left side of the board. In this manner, the status block of the card is visible.

Work Center Information

When a discrepancy is received by the work center supervisor, pertinent data is recorded on the work center register. The supervisor informs maintenance control of the ETC, WUC, and the number of men that will be assigned to the task. The register is then placed in the pocket under the heading IN WORK and parallel to the name of the person given responsibility for the task. A distinguishing tab (or number) can be placed in any corresponding pocket(s) of other personnel assigned to the repair action. The register remains on the board until the discrepancy has been completed or it is necessary to go AWP or PENDING. If either of these two conditions occur, the register is removed from the IN WORK section, annotated with the proper information, and maintenance control is notified of the work status change. The register is then placed either in the AWP or in the PENDING section of the work center board. When the material has been

13178

CHAPTER 3

SAFETY

In the performance of his normal duties, the naval avionics technician is exposed to many potentially dangerous conditions and situations. No training manual, no set of rules or regulations, no listing of hazards can make working conditions completely safe. However, it is possible for the technician to complete a full naval career without serious accident or injury. Attainment of this goal requires that he be aware of the main sources of danger, and that he remain constantly alert to those dangers. He must take the proper precautions and practice the basic rules of safety. He must be safety conscious at all times, and this safety consciousness must become second nature to him.

Much pertinent safety information is contained in Rate Training Manuals. Of particular worth among these manuals are Airman, NavPers 10307-C, and Standard First Aid Training Manual, NavPers 10081-B. In addition, directives concerning safety are published by all major commands on those specific hazards and procedures falling under the cognizance of those commands. The Chief of Naval Operations has recently issued a listing of specific safety precautions compiled by the Navy Department. This publication cross references safety directives by subject matter and by the identifying designation.

The purpose of this chapter is to indicate some of the major hazards encountered in the normal working conditions of the technician, and to indicate some of the basic precautions that must be observed. Although many of these hazards and precautions are general and apply to all personnel, some of them are peculiar or especially applicable to avionics maintenance personnel.

SAFETY PRECAUTIONS

Most accidents which occur in noncombat operations can be prevented if the full cooperation of personnel is gained, and if care is exercised to eliminate unsafe acts and conditions. In the following paragraphs, some general safety rules are listed. These rules apply to personnel in all types of activities, and each individual should strictly observe the following precautions as applicable to his work or duty:

1. Report any unsafe condition or any equipment or material which he considers to be unsafe.
2. Warn others whom he believes to be endangered by known hazards or by failure to observe safety precautions.
3. Wear or use available protective clothing or equipment of the type approved for safe performance of his work or duty.
4. Report any injury or evidence of impaired health occurring in the course of work or duty.
5. Exercise, in the event of any unforseen hazardous occurrence, such reasonable caution as is appropriate to the situation.

Safety precautions in this chapter are not intended to replace information given in instructions or maintenance manuals. If at any time there is doubt as to what steps and procedures to follow, consult the leading petty officer.

AVIATION SAFETY

For purposes of this discussion, the term AVIATION SAFETY is used in connection with all functions and operations having to do with aircraft and with materials and equipment used in connection with aircraft, hangars, parking areas and ramps, and flight lines and taxiways.

13180

Hazards

Among the major hazards present in aviation activities are the following:

1. Fire or explosion caused by the application of external or internal power to an aircraft which is in some state of malfunction or disrepair, or undergoing maintenance or modification; or which create explosive vapors; or which have electrical short circuits.

2. Personal injuries sustained in falling from aircraft or workstands, being burned or blown about by jet blast or prop wash, being struck by objects blown about by jet blast or prop wash, being sucked into jet intakes, or being struck by propeller or rotor blades.

3. Being run down or over, due to lack of alertness to the movement of taxiing aircraft or ground equipment vehicles.

4. Explosion of aircraft batteries due to improper charging methods or to current overloading on ground tests within an aircraft.

5. Injuries (especially common during the hours of darkness) caused by encounter with tiedown lines, padeyes, chocks, protruding parts of aircraft or other equipment, or other such items about a deck or ramp.

6. Canopy, ejection seat, ordnance, and other "wrong switch at the wrong time" type accidents.

7. Misuse of, and abuse to, flight safety equipment, parachutes, "Mae Wests," liferafts, etc.

8. Accidents caused by careless workmanship, such as leaving tools or other extraneous materials in aircraft bilges, engine nacelles, intake or exhaust ducts, or movable parts of aircraft structures.

Precautions

Many safety precautions are of general nature and apply to all types of aircraft; however, others vary in specific details between specific models. It is imperative that all personnel whose duties take them into the vicinity of aircraft be familiar with both general safety precautions and with the specific precautions for the model with which they are associated. The following partial list of safety precautions is not intended to represent a complete listing. It is intended to serve merely as a guide to illustrate the general types of safety items which must be included in the safety education and training programs of all aviation activities.

1. Appropriate warning signs must be placed in or around aircraft or work areas whenever and wherever an unsafe condition is known or thought to exist. Strict attention and adherence to the signs must be enforced.

2. Smoking regulations and prohibitions must be observed and strictly enforced. Since explosive vapors may be ignited from any source of open flame or from electrical arcing, these conditions are subject to the same restrictions as smoking.

3. Radio and radar transmitters should not be trained on potentially explosive areas or on personnel, nor should they be operated in close proximity to flammable or explosive materials or vapors. This hazard is discussed in considerable detail in a later portion of this chapter.

4. Storage batteries or electric cables should not be disconnected or removed from their circuits in any enclosed space immediately following flight or fueling operations without first ventilating the space to remove accumulated vapors. All switches should be opened and all electric power disabled prior to disconnecting batteries or electric cables.

5. Combustible materials such as rags and clean waste should be stowed in covered metal containers. Used waste and rags should never be discarded near aircraft; they should be put into plainly marked metal containers.

6. Aircraft should be parked with parking brakes set, chocks in place, and tiedowns installed. If manila rope is used for tiedowns, some slack must be allowed; manila rope will shrink when wet, and may result in undue strain on the aircraft.

7. During jet engine runup, foreign objects may be drawn into the intake ducts, causing damage to the engine compressor section and the danger of flying debris from the exhaust section. During maintenance procedures involving engine operation, a careful inspection of the intake ducts and surrounding areas must be performed to insure the absence of foreign objects; and engine air intake safety screens must be properly installed. Parking areas, turnup areas, taxiways, and runways

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

must be kept clean and free of stones, hardware, and other foreign objects.

MACHINERY

When working with, on, or around machinery, be constantly alert to moving parts. Never reach into the path of moving parts of a machine, either with the hands or with any other item. Always follow prescribed procedures in making adjustments on machinery while in operation; if at all possible, make the adjustments with the machinery shut down. Never wear loose, baggy, or ill-fitting clothing in the immediate vicinity of machinery. Remove rags, papers, etc., from pockets; remove ties, wristwatches, rings, etc.; button shirt sleeves; make sure dogtags are inside the undershirt or removed completely.

ELECTRICAL EQUIPMENT

The safety precautions and considerations listed above for machinery apply also to electrical equipment. In addition to the danger of being grabbed or struck by moving parts, electrical equipments also present the dangers of fire, explosion, electrical shock, and burns.

Electrical equipment should never be operated in areas where explosive vapors are present or suspected, unless the equipment is of the special explosion-proof designs made expressly for use in such areas.

When working with, on, or around electrical equipment, avoid contact with power circuits. If it is necessary to work on energized circuits or on electrical equipment while in operation, use adequate protective materials (rubber gloves, insulated tools, insulating matting, etc.) and extreme care. Never work on electrical equipment when standing in water, when perspiring heavily, or when in contact with metal decks or other metallic structures or equipment. When preparing to work on deenergized electrical circuits, make sure the power switch is off, and then use a grounding probe to eliminate any residual charge that may exist in the circuit.

These precautions apply to low voltage equipments as well as to high voltage equipments. It must be remembered, in connection with electrical shock and burns, that it is the current that does the damage, not the voltage.

VOLATILE FLUIDS

Volatile fluids are liquids which evaporate rapidly at relatively low temperatures. In this discussion, the term will be used to include pressurized gases escaping from their containers. In safety considerations, two main types of fluids must be considered: First, those which result in explosive vapors; and second, those which are toxic.

Explosive Vapors

Aviation fuels, alcohol, painting materials and supplies, insulating varnish, certain cleaning supplies, and many industrial gases produce potentially explosive vapors when allowed to accumulate in closed spaces. The hazards relating to these materials are associated with the FLASHPOINT of the liquid. This is the lowest temperature at which the liquid gives off vapor which accumulates near the surface in sufficient quantity to form a combustible mixture with air. Although liquid oxygen does not have a flashpoint, the explosive effect is the same. Almost any material that will oxidize becomes highly explosive when in the presence of liquid oxygen.

The flashpoint varies with specific materials. Personnel working with volatile materials should become familiar with the characteristics of the particular materials with which they are associated. They should know the flashpoint and also the concentration which constitutes a combustible mixture.

A general safety rule regarding explosive vapors is to always provide adequate ventilation so as to prevent accumulation of vapors, or to dispel accumulated vapors prior to operating electrical equipment in that space. The presence of an odor of gasoline or other flammable or explosive vapors is not a reliable indicator of flammability, since the ability to detect odors varies between observers.

Toxic Vapors

Some liquids, upon evaporating, produce vapors which are harmful to personnel. Carbon

CHARACTERISTICS OF CUCURBIT VIRUSES

Virus	Distribution	Importance in Arizona	Transmission	SYMPTOMS		
				Squash & Cucumber	Cantaloupe	Watermelon
Cucumber Mosaic Virus CMV	Restricted to areas near towns, dooryard gardens or sugar beet fields.	Very important when present.	Aphids	Severe stunt, chlorosis, mosaic. Fruit distorted, discolored.	Severe stunt, mosaic, chlorotic mottle in leaves, fruit size reduced.	Infection rare
Watermelon mosaic virus WMV	Most widespread of cucurbit viruses.	Most important in state as a whole.	Aphids	Mild stunt mosaic in leaves, fruit distorted, discolored.	Mild stunt mosaic and severe leaf distortion. Fruit size reduced.	Mild stunt, mosaic and occasionally severe leaf distortion, fruit size may be reduced.
Curly Top virus CTV	Sporadic in central Arizona. Rare in Yuma area.	Very important when present.	Leafhopper	Severe stunt. Late infections produce less damage.	Severe stunt. Late infections cause less damage.	Severe stunt when infected early.
Squash mosaic virus SMV	Very limited in Arizona.	On squash only, when present.	Cucumber beetles, seed.	Stunt, severe leaf distortion, fruit distorted, discolored.	Mild mottle, little damage.	No infection.
Watermelon Stunt Strain of SMV WSV	Very limited except in fall months.	On squash and watermelon only, when present.	Cucumber beetles, seed.	Relatively mild leaf mosaic, fruit distorted, discolored.	Green vein banding, initial symptoms later fade away.	Very severe stunt, chlorosis and necrosis.
Cucurbit latent virus CLV	Very widespread.	Not known but seems to be of little importance.	Aphids	No visible symptoms, infection does occur.	No visible symptoms, infection does occur.	No visible symptoms, infection does occur.

1315

tetrachloride is an effective solvent, an excellent cleaning material, and an excellent fire extinguisher—but it produces vapors so toxic that its use for any purpose is specifically prohibited by Navy directives. Many other materials are either prohibited or very rigidly limited for use. In most instances, the precautions are listed on the container. These precautions must at all times be rigidly adhered to and enforced. Safe substitutable materials should be used whenever permissible.

Safety considerations require that all personnel make themselves familiar with the hazards involved in the use of all materials. Toxic materials and vapors may be easily detectable, or they may be almost completely undetectable; they may act very slowly, or they may act almost instantly; they may cause discomfort, temporary damage, permanent injury, or even death; they may or may not be explosive in addition to being toxic. Toxic vapors may produce headache, dizziness, nausea, and a general feeling of illness. They may cause a gradual loss of interest, energy, or awareness. They may result in unconsciousness. They may cause temporary or permanent damage to the respiratory system, eyes, or skin. They may cause paralysis or death. Avoid prolonged exposure to vapors not known to be safe.

CONFINED SPACES

When personnel are working in confined spaces, adequate ventilation must be provided. This includes oxygen for normal breathing, cooling to prevent heat exhaustion, air movement and exchange to prevent hazardous accumulations of vapors, and an additional or alternate source of ventilation for use in the event of emergency. Whenever a worker is sent into a confined space for any reason, provisions should be made in advance for his rescue in the event of accident or emergency. These provisions include the use of safety lines for locating the worker and for retrieving him from the space. Some means of communication must be established so that the conditions existing inside and outside the space may be made known to personnel concerned. A safety man must be provided to keep a constant check on the condition of the space and the worker, and he must be prepared to sound the alarm for additional help or to render assistance to the worker in the confined space, as required.

Fumes tend to collect in confined spaces, so the condition of the space should be checked prior to entry. The worker should also check conditions as he enters and monitor them during his stay. He should maintain constant communication with his safety man and inform him of any abnormal conditions that may exist.

Equipment used by personnel working in confined spaces is a matter of considerable importance. Enough light should be provided so that he can see clearly what he is doing. The light provided should be insulated so that it does not present a shock hazard (confined spaces are usually quite warm, and a safety light produces additional heat, so perspiration may become a serious problem). When possible, explosion-proof equipment should be used in confined spaces, and protective clothing should be used if toxic fumes are known or suspected to exist within the space.

TOOLS

To prevent tragic and unnecessary damage to aircraft or equipment, loss of human life, or personal injury, it is necessary to develop and to practice careful, safe, and clean work habits. All tools and equipment used should conform to Navy standards as to quality and type, and should be used only in the manner and for the purpose intended. All tools in active use should be maintained in good repair, and all damaged or nonworking tools should be replaced through supply channels. When a job is completed, or when work is interrupted, all tools should be counted and returned to the toolboxes or to the tool issue room. This should be done as carefully as a surgeon accounts for all his instruments following a major operation.

Handtools

Detailed information on the use, care, and selection of general tools is contained in the Rate Training Manual, Basic Handtools, NavPers 10085-A. Chapter 7 of this course presents information on specific tools used by avionics technicians. Appropriate study and frequent review of these sources are recommended for all personnel using or supervising

13183

the use of tools. The following paragraphs point out a few malpractices sometimes found among maintenance personnel.

Care should be taken in selecting the proper type pliers or cutters for the specific job. Pliers or cutters should not be used on nuts or pipe fittings–wrenches are made for this purpose. When cutting short pieces of wire, rivets, or other materials, take precautions that the clippings do not fly and cause eye injury; wear goggles and be careful.

A screwdriver used for electrical work should have a nonconducting handle. Screwdrivers should never be used as a substitute for a punch, chisel, or prybar. The screwdriver selected should be of the proper type and size for the screw on which it is to be used. The tip of the screwdriver should be kept in the proper shape and condition–broken or defective screwdrivers should be discarded and replaced.

Wrenches should be used only if they are in good condition and if they are right for the job. Never use a wrench as a hammer, and never put an extension on the handle to increase torque. An adjustable wrench should be used so that the movable jaw is forward in the direction of turning. When working in close spaces, use a grip that will not endanger the fingers and knuckles if the wrench should slip.

Portable Power Tools

All portable power tools should be carefully inspected prior to use to insure that they are clean and in the proper state of repair. Switches should operate in a normal manner, cords should be free of defects, and the casings of all electrically driven tools should be properly grounded. When using or preparing to use any portable power tools, the cords, hoses, or cables should not be allowed to kink, nor should they be left where they may be run over or constitute a tripping hazard. They should not be allowed to come into contact with oil, grease, hot surfaces, chemicals, or sharp objects. When damaged, they should be replaced, never patched with tape.

Sparking electric power tools or equipment should never be used in any space where flammable vapors, gases, liquids, or explosives are suspected. When unplugging electrical tools or equipment from receptacles, first turn the equipment off, then grasp the plug (not the cord) to remove the plug from the receptacle. Stow the tool in its proper place.

ELECTRIC DRILL.–When using a portable power drill, grasp it firmly during operation to prevent bucking or breaking loose with possible injury to the user or damage to the tool or material. Use only straight, undamaged, and properly sharpened drill bits. Tighten the bit securely in the chuck, using the key provided (never tighten the chuck with wrench or pliers). The bit should be set straight and true in the chuck and the work firmly clamped. When drilling metal, the work should be marked with a center punch before beginning the drilling operation.

SOLDERING IRON.–The soldering iron is a fire hazard and a potential source of burns. Always assume that a soldering iron is hot; never rest the iron anywhere but on a metal surface or rack provided for that purpose. Keep the iron holder in the open to minimize the danger of fire from accumulated heat. Do not swing or flip the iron to dispose of excess molten solder–a drop may strike someone, or strike the equipment and cause a short circuit. Keep the head and hands away from the hot end of the iron; hold small soldering jobs with pliers or clamps. Position the ends of wires and cables so that they do not endanger the face or the eyes; never flip the wires to remove excess solder. When cleaning the iron, place the cleaning rag on a suitable surface and wipe the iron across it–do not hold the rag in the hand. Disconnect the iron when leaving the work, even for a short time–the delay may be longer than planned.

GROUNDING.–A poor safety ground, or one that is wired incorrectly, is more dangerous than no ground at all. The poor ground is dangerous because it does not offer full protection, while the user is lulled into a false sense of security. The incorrectly wired ground is a hazard because one of the line wires and the safety ground are transposed, making the shell of the tool "hot" the instant the plug is connected. Thus the unwary user is trapped, unless by pure chance the safety ground is connected to the grounded side of the line on a single-phase grounded system, or no grounds are present on an ungrounded system. In this instance the user again goes blithely along using the tool until he encounters a receptacle which has its wires transposed or a ground appears on

13185
13184

the system. Because there is no absolutely foolproof method of insuring that all tools are safely grounded (and because of the tendency of the average sailor to ignore the use of the grounding wire), the old method of using a separate external grounding wire has been discontinued. Instead, a 3-wire, standard, color-coded cord with a polarized plug and a ground pin is required. In this manner, the safety ground is made a part of the connecting cord and plug. Since the polarized plug can be connected only to a mating receptacle, the user has no choice but to use the safety ground.

All new tools, properly connected, use the green wire as the safety ground. This wire is attached to the metal case of the tool at one end and to the polarized grounding pin in the connector at the other end. It normally carries no current, but is used only when the tool insulation fails, in which case it short circuits the electricity around the user to ground and protects him from shock. The green lead must never be mixed with the black or white leads which are the true current-carrying conductors.

Check the resistance of the grounding system with a low reading ohmmeter to be certain that the grounding is adequate (less than 0.1 ohm is acceptable). If the resistance indicates greater than 0.1 ohm, use a separate ground strap.

Some old installations are not equipped with receptacles that will accept the grounding plug. In this event, use one of the following methods:

1. Use an adapter fitting.
2. Use the old type plug and bring the green ground wire out separately.
3. Connect an independent safety ground line.

When using the adapter, be sure to connect the ground lead extension to a good ground. (Do not use the center screw which holds the cover plate on the receptacle). Where the separate safety ground leads are externally connected to a ground, be certain to first connect the ground and then plug in the tool. Likewise, when disconnecting the tool, first remove the line plug and then disconnect the safety ground. The safety ground is always connected first and removed last.

GENERAL HAZARDS

In addition to the specific hazards encountered in electronic maintenance and the obvious dangers involved in falling, tripping, slipping, colliding, etc., the technician is concerned with other general classes of hazards. The following paragraphs, although by no means a complete coverage, will present some pertinent details and general information concerning a few of the most important ones.

FIRE AND EXPLOSION

Although fire and explosion are frequently associated with one another, they may also exist separately. Considerable detail on these subjects is included in Basic Military Requirements, NavPers 10054-B. Study and review of this material will provide a foundation for the specific information presented in this part of this chapter. Information is available in other Navy Training Courses, including the following: Seaman, NavPers 10120-E; Airman, NavPers 10307-C; Military Requirements for Petty Officer 3 & 2, NavPers 10056-B; and Standard First Aid Training Course, NavPers 10081-B.

Fire

A general discussion of the nature of fire, the classes of fires, firefighting systems and equipment, protective clothing and equipment, and fire prevention is contained in chapter 14 of the Rate Training Manual, Basic Military Requirements, NavPers 10054-B. General information concerning aircraft crash rescue and firefighting is found in chapter 15 of Airman, NavPers 10307-C. Specific details relating to firefighting and rescue procedures for a particular model aircraft may be found in the technical manuals published for that model aircraft. Standard First Aid Training Course, NavPers 10081-B, contains general procedures for the rescue of personnel from fire and first aid treatment for fire victims. A thorough study and a review of these references are an obligation of all personnel. Since this material is found in publications which are generally available to

13185

naval aviation personnel, it is not presented in detail in this course. However, some details of special interest are summarized in the following paragraphs.

In the case of electrical fires, the following steps should be taken:

1. Deenergize the electrical circuit involved, and any other electrical circuits that may interfere with the proper control or extinguishing of the fire, or which may constitute a hazard to the firefighters.

2. Call the fire department. This should be done even if it is a "small fire" that can be "easily" controlled or extinguished. This is a precautionary measure to be taken in the event of unforeseen complications or miscalculation.

3. Attempt to control or extinguish the fire if possible, using the appropriate fire extinguisher and firefighting procedure.

4. Make a full report on the fire to the appropriate authority. The fire marshal has complete information as to the proper forms and reports, and should be contacted for assistance if needed. However, this does not relieve the person discovering the fire from his responsibility in this matter.

For combating electrical fires, a CO_2 (carbon dioxide) fire extinguisher is best. The carbon dioxide should be directed to the base of the flame, where it will serve two purposes: It cools the area, and it decreases the percentage of oxygen present at the fire. However, for major fires of any type in confined spaces, the excessive use of carbon dioxide may be dangerous, due to the decreasing of oxygen content.

Carbon tetrachloride should not be used for firefighting, because it is converted into phosgene gas (a deadly poisonous gas) upon contact with hot metals. Even in open spaces this gas creates a serious hazard, and the use of carbon tetrachloride is specifically prohibited.

Application of water to electrical fires may be dangerous to personnel and injurious to equipment, because of the electrical conductivity of water and the corrosive properties of water when used on metallic substances.

Foam type fire extinguishers should not be used on electrical fires because the foam is electrically conductive.

Avoid inhaling flames or smoke from fires, as these may cause serious injury or death if breathed to excess.

Special precautions must be taken if the fire is in an enclosed or confined space. Local regulations will detail the appropriate procedure to be followed in this event.

In the case of cable fires in which the inner layers of insulation (or insulation covered by armored or shielded cable) are burning, the only positive method of preventing the fire from running the length of the cable is to cut the cable and separate the ends.

Fumes of an explosive, toxic, or corrosive nature are generated in the combustion of certain substances. This will be discussed in a later portion of this chapter.

Explosion

Explosion may be caused by fire or may be the cause of a fire—or the two may be unrelated. It may be the result of a chemical action, heat, mechanical malfunction, or other causes. An explosion is generally accompanied by a loud noise and a sudden buildup pressure. Several types of explosions are of interest to the technician in the performance of his normal duties.

The accumulation of combustible fumes or vapors from fire or from evaporating liquids represents a potential hazard. A spark or increase in heat from any cause or certain chemical combinations, may trigger the explosion.

An explosion in the presence of fire may result in the rapid spread of that fire. An explosion in the presence of combustible materials may cause a fire to start.

An explosion may result in flying debris which will act as shrapnel and may cause severe personnel injuries. In the event of severe explosion, nearby personnel may suffer from the concussion effect of the blast.

In addition to the fire-caused accumulation of combustible vapors and the accumulation of combustible gases in the vicinity of fire or electric sparking, there are several other explosion hazards. A few of these are discussed in the following paragraphs.

Some equipments are pressurized and are susceptible to explosion in the event of excessive pressurization or mechanical failure of any part of the pressurized system. In this event, the major hazard of the explosion is the creation of shrapnel, or the increased danger of arcing in the absence of the pressurization. Implosion,

13186

like explosion, results in creation of shrapnel, frequently with toxic materials coating the splinters. The rapid collapse of glass vacuum tubes is an example of implosion which is of prime importance to electronics personnel.

Explosive ordnance devices are sometimes installed on aircraft or placed adjacent to the aircraft preparatory to loading. Accidental operation of switches may result in the firing of these devices. The technician, when operating any equipment in the aircraft, must keep himself constantly aware of any electrically initiated ordnance devices in the vicinity of his aircraft, and must observe all precautions which apply to the situation. When missiles or weapons are installed, only fully qualified personnel should be permitted to operate any electronic equipment in the aircraft. A definite possibility of detonation of ordnance devices by radiated RF energy is also known to exist. This hazard is discussed later in the chapter under RF radiation hazards.

FUMES

The term FUMES refers to vapors, gases, or smoke, especially those that are strong or dangerous, or which have a potent odor. For purposes of this discussion, fumes may be classified as toxic, explosive, corrosive, poisonous, suffocating, or irritating. They may result from fire, evaporating liquids or solids, chemical action, or overcrowding in confined or poorly ventilated spaces. They may be easily detectable, or almost impossible to detect. They may represent a single hazard, or they may represent a combination of several distinct hazards.

Fuels

The vapors from nearly all hydrocarbon fuels present hazards of fire and explosion as previously discussed; in addition, they are toxic. When breathed in heavy concentration, or for prolonged periods, they may result in permanent damage to the respiratory system, loss of consciousness, paralysis, and/or death. For these reasons, numerous safety regulations and detailed procedures have been issued regarding fuels and fueling operations. In general, the most important of these regulations require rigid enforcement of the NO SMOKING rules, adequate ventilation, restrictions on the use of electrical equipment, use of special equipment, and the presence of manned firefighting equipment.

Painting Supplies and Materials

Most paints and thinners, and many other painting supplies, emit vapors which are both flammable and toxic. Regulations require these items to be stored in closed containers in a noncombustible enclosure isolated from living, working, or ordinary storage spaces. Use of the material is restricted to well-ventilated areas, and in many cases, special equipment and clothing are made available for use.

Battery Fumes

In the standard lead-acid storage battery, explosive fumes are generated by chemical action. In the charging operation, hydrogen is released. Hydrogen is a highly combustible gas, which is violently explosive when in strong concentration. The newer nickle-cadmium batteries do not present this hazard, but do present other hazards as covered in a later discussion. Battery lockers are subject to very strict safety regulations with special emphasis on smoking restrictions and ventilation requirements.

Smoke

Smoke, a byproduct of fire, represents a toxic and suffocating hazard. In addition, there are other fumes frequently present in smoke. These fumes, products of combustion or of increased evaporation, may be poisonous, corrosive, or explosive. It has been previously mentioned that carbon tetrachloride, upon coming into contact with hot metals, is converted into deadly phosgene gas. There are many other materials which are converted by heat or combustion from relatively harmless substances into lethal fumes.

Carbon monoxide is present in nearly all smoke, and is the most common cause of "smoke poisoning" among firefighters and fire victims. Unless the victim is removed from the smoke and administered artificial respiration and/or oxygen, death may result.

13187

The use of gas masks, breathing apparatus, and safety lines is prescribed under certain firefighting situations.

Miscellaneous Materials

Many other general classes of materials contain substances which produce hazardous fumes. These materials should be used only according to specified procedures. Some of these material classes are cleaning materials, insecticides, preservatives, solvents, adhesives, and finishes.

Although not technically classified as fumes, dust and small particles from grinding operations present similar hazards and require precautions similar to those taken for fumes.

CHEMICALS

The subject of chemical warfare (and its agents, treatments, and preventive measures) is treated in detail in Navy Training Manuals for which the prospective PO 3 or 2 is responsible. Among these manuals are Basic Military Requirements, NavPers 10054-B; Military Requirements for Petty Officer 3 & 2, NavPers 10056-B; and Standard First Aid Training Course, NavPers 10081-B.

RADIOACTIVITY

Radioactive materials are in common usage throughout the Navy, and particularly in the electronics field. Common radioactive materials familiar to most technicians include the luminous dials on watches and various instruments, and the luminescent markings on equipment. Radioactive material is intentionally added to many special purpose electron tubes to produce a continuous supply of ionized particles to insure that the tube will always ionize at the same voltage. The principal radioactive materials contained in these tubes include certain isotopes of carbon (C^{14}), cesium (Cs^{137}), cobalt (Co^{60}), nickel (Ni^{63}), and radium (Ra^{226}). These tubes are usually the TR and ATR tubes, glowlamp and cold cathode type tubes, and certain spark gap tubes. With proper precautions and procedures, these materials present no serious hazard; with careless or improper treatment, however, the hazard may become very serious.

Radioactive materials emit rays which may cause changes in living tissue with subsequent injury to the body. The amount of change, and therefore the seriousness of the injury, increases with the amount of radiation absorbed. The absorption of radiation is cumulative, and the repair of damaged tissue is slow; therefore, the hazard level is based on the total amount of radiation absorbed as well as on the rate of absorption.

The primary hazard considered in this discussion is injection of radioactive substances into the bloodstream through a cut or an abrasion, or through penetration of the skin by glass slivers from broken tubes. This type injury may be quite serious, even with minute quantities of radioactive materials injected. The materials injected are carried throughout the body by the bloodstream, and tend to accumulate in certain organs or parts of the body. In addition to the radiation effects, they also cause a type of poisoning similar to chemical poisoning.

A wound caused by a radioactive particle requires treatment by a medical officer as soon as possible, regardless of the size of the wound. The hazard of radioactive particles being left in a wound CANNOT BE IGNORED.

There are no known antidotes for poisoning from radioactive particles which remain in the body. Treatment of radiation sickness is complicated and lengthy. Even with the best medical attention, the results are often inconclusive. However, progress continues in this field and close liaison with the medical department will insure that the latest first aid procedures and medical treatment are used.

Inhalation of minute particles of radioactive dust can cause coating of the mucous membranes, with resultant poisoning and increased radiation effects. Once lodged in the nasal passages or throat, these particles are very difficult to remove–in the lungs they are even more difficult.

Contamination of the skin by radioactive materials may produce radiation burns resembling the temporary redness of a mild sunburn (or in severe cases, a serious flame burn which destroys the skin). All such cases should be reported to the medical authorities immediately; with proper medical care, complete recovery may be expected except in extreme

13188

cases involving severe burns over an extensive area. This type injury is rare.

Detection

Radioactive radiation is completely undetectable through use of the human senses; detection relies upon the use of special equipment. The methods of detection and the types of radioactivity detectors are discussed in chapter 15 of the Rate Training Manual, Basic Military Requirements, NavPers 10054-B. Coverage of the subject in this course is limited to a brief discussion of the various conditions and places which require monitoring.

Storage areas containing instruments, equipments, or tubes with radioactive materials should be monitored periodically to insure that the radiation level does not exceed allowable limits. Specifically, the air intake and exhaust screens or filters should be monitored prior to cleaning. All areas surrounding the breakage of any tube containing radioactive material, or the flaking of radioactive paint or markings, should be monitored to help locate all the radioactive material. These areas should be monitored again following decontamination to determine the effectiveness of the procedures used. Personnel should be monitored whenever contact with radioactive materials is suspected, or following participation in decontamination activities.

Precautions

The following safety practices should be observed to minimize the hazard present by radioactive materials:

1. Tubes or instruments should not be removed from cartons until immediately prior to actual installation. This serves two purposes—to prevent accidental breakage, and to avoid the possibility of concentrating several radioactive sources in a small volume (which would increase the effective intensity of radiation).

2. When a radioactive component is removed from equipment, it should be placed in an appropriate carton to prevent possible breakage.

3. Items containing radioactive materials should never be carried in a pocket or elsewhere about the person in a manner that flaking or breakage can occur.

4. Extreme care should be exercised in the handling of these items while installing or removing them from equipment.

5. Tubes should never be broken intentionally; however, if breakage does occur, material contaminated by radioactivity should not be allowed to come in contact with any part of the body at any time. Take care to avoid breathing any dust or vapor (such as radon gas, a highly radioactive substance) which may be released by such breakage. Immediately locate all broken pieces, and isolate the area until the broken pieces have been removed or declared nonradioactive by test with an adequate radiation-sensitive device.

6. No food or drink should be brought into the contaminated area or near any radioactive material.

7. Immediately after leaving a contaminated area, personnel who have handled radioactive material in any way should remove contaminated clothing. They should wash their hands and arms thoroughly with soap and water, especially before eating, drinking, or smoking.

8. When a wound caused by a sharp radioactive object is sustained, report to medical authorities for treatment as soon as possible.

Decontamination and Disposal

When cleaning a contaminated area, rubber or plastic gloves should be worn. Large fragments of a broken tube should be removed with the aid of some tool such as forceps, if they are available. The remaining particles can be removed with a vacuum cleaner, using a disposable collecting bag, or by wiping a wet cloth across the area. (If the breaking of tubes is a frequent occurrence, care should be given to selecting the best type of collecting bags.)

If a wet cloth is used, make one stroke at a time, and fold the cloth in half after each stroke, always using a clean side. When the cloth becomes too small, discard it and continue with a clean piece. Be careful not to rub the radioactive particles into the surface by using a back-and-forth motion. All debris, cloths, and bags used for cleaning should be sealed in a container such as a plastic bag, heavy waxed paper, or a glass jar, and placed in a steel can for disposal.

13189

Radioactive waste materials and sweeper bags should not be disposed of individually. They should be collected in a designated steel container with a tight-fitting lid and suitable marking until a reasonable quantity for disposal has been gathered. Containers for radioactive materials should be marked with the radiation symbol. (See fig. 3-1.) The symbol is printed in magenta (purplish shade of red) color on a yellow background.

Radioactive waste can be disposed of by burying in soil or by sinking in the ocean. Detailed information concerning the disposal of radioactive materials is contained in BuShips Instruction 5100.15.

ELECTRICAL HAZARDS

Every person who works with electronic equipment should be constantly alert to the hazards of the equipment to which he may be exposed, and also be capable of rendering first aid to injured personnel. The installation, operation, and maintenance of electronic equipment requires enforcement of a stern safety code. Carelessness on the part of the operator or the maintenance technician can result in serious injury or death due to electric shock, falls, burns, flying objects, etc. After an accident has happened, investigation almost invariably shows that it could have been prevented by the exercising of simple safety precautions and procedures with which the personnel should have been familiar.

Each man concerned with electronic equipment should make it his personal responsibility to read and become thoroughly familiar with the safety practices and procedures contained in applicable safety directives, manuals, and other publications, and in equipment technical manuals prior to performing work on electronic equipment. It is the individual's responsibility to identify and eliminate unsafe conditions and unsafe acts which cause accidents.

AT.13

Figure 3-1.—Radiation symbol.

INJURIES FROM ELECTRICITY

Damage to the body may be caused by the passage of electric current over the skin or through the body. In any case, it is important to remember that it is the current, not the voltage, that causes the damage. This current, if of sufficient magnitude, may cause asphyxiation, burns, and/or shock. Because individuals differ in susceptibility to electrical shock and its associated hazards, exact figures are hard to determine.

However, the current magnitude resulting from application of any voltage varies inversely with resistance. When dry, the body has a comparatively high resistance. When moist, however, body resistance is greatly reduced. Even "low voltage" can be extremely hazardous under conditions of heavy perspiration or damp surroundings.

Symptoms of electric shock, and procedures for rescue of electric shock victims are discussed in Standard First Aid Training Course, NavPers 10081-B. Since this topic is of such great importance to all personnel involved in electronics, that material should be studied with great care.

GENERAL PRECAUTIONS

Take time to be safe when working on electronic circuits and equipment. Carefully study the schematics and wiring diagrams of the entire system, noting what circuits must be deenergized in addition to the main power supply. Remember that electronic equipments frequently have more than one source of power. Be certain that ALL power sources are deenergized before servicing the equipment. Do not service any equipment with the power on unless it is necessary.

It must be borne in mind that deenergizing main supply circuits by opening supply switches will not necessarily "kill" all circuits in a given piece of equipment. A source of danger that has often been neglected or ignored—sometimes with tragic results—is the inputs

13190

to electronic equipment from other sources, such as synchros, remote control circuits, etc. For example, turning off the antenna safety switches will disable the antenna, but it may not turn off the antenna synchro voltages from other sources. Moreover, the rescue of a victim shocked by the power input from a remote source is often hampered because of the time required to determine the source of power and turn it off. Therefore, turn off ALL power inputs before working on equipment.

Remember that the 115-volt power supply voltage is not low, relatively harmless voltage, but is the voltage that has caused more deaths in the Navy than any other.

Do NOT work with high voltage circuits by yourself; have another person (safety observer), who is qualified in first aid for electrical shock, present at all times. The man stationed nearby should also know the circuits and switches controlling the equipment, and should be given instructions to pull the switch immediately if anything unforeseen happens.

Always be aware of the nearness of high voltage lines or circuits. Use rubber gloves where applicable, and stand on approved rubber matting (MIL-M-15562). Not all so-called rubber mats are good insulators.

Equipment containing metal parts, such as brushes and brooms, should not be used in an area within 4 feet of high voltage circuits or any electric wiring having exposed surfaces.

Inform remote stations as to the circuit on which work is being performed.

Keep clothing, hands, and feet dry if at all possible. When it is necessary to work in wet or damp locations, use a dry platform or wooden stool to sit or stand on, and place a rubber mat or other nonconductive material on top of the wood. Use insulated tools and insulated flashlights of the molded type when required to work on exposed parts.

Do not wear loose or flapping clothing. The use of thin-soled shoes with metal plates or hobnails is prohibited. Safety shoes with nonconducting soles should be worn if available. Flammable articles, such as celluloid cap visors, should not be worn.

When working on electronic or electrical apparatus, technicians should first remove all rings, wristwatches, bracelets, ID chains and tags, and similar metal items. Care should be taken that the clothing does not contain exposed zippers, metal buttons, or any type of metal fastener.

Do NOT work on energized circuits unless absolutely necessary. Be sure to take time to lock out (or block out) the switch and tag it. Locks for this purpose should be readily available; if a lock cannot be obtained, remove the fuse and tag it.

Use one hand when turning switches on or off. Keep the doors to switch and fuse boxes closed except when working inside or replacing fuses. Use a fuse puller to remove cartridge fuses after first making certain that the circuit is dead.

All supply switches or cutout switches from which power could possibly be fed should be secured in the OPEN (safety) position and tagged. The tag should read "THIS CIRCUIT WAS ORDERED OPEN FOR REPAIRS AND SHALL NOT BE CLOSED EXCEPT BY DIRECT ORDER OF _____" (the person making, or directly in charge of, repairs).

Never short out, tamper with, or block open an interlock switch. Keep clear of exposed equipment; when it is necessary to work on it, use one hand only as much as possible.

Warning signs and suitable guards should be provided to prevent personnel from coming into accidental contact with high voltages.

Avoid reaching into enclosures except when absolutely necessary; when reaching into an enclosure, use rubber blankets to prevent accidental contact with the enclosure.

Do not use bare hands to remove hot tubes from their sockets. Use asbestos gloves or a tube puller.

Use a shorting stick, similar to the one shown in figure 3-2, to discharge all high voltage charges. Before a worker touches a capacitor or any part of a circuit which is known or likely to be connected to a capacitor (whether the circuit is deenergized or disconnected entirely), he should short circuit the terminals to make sure that the capacitor is completely discharged. Grounded shorting sticks should be permanently attached to workbenches where radar equipment and other types of electronic devices using high voltages are regularly serviced.

Make certain that the equipment is properly grounded. Ground all test equipment to the equipment under test.

OCIEI
13191

AT.14

Figure 3-2.—Shorting stick.

Turn off the power before connecting alligator clips to any circuit.

When measuring circuits over 300 volts, do not hold the test prods.

Transmitter adjustments should not be made while the equipment is energized unless the adjustments can be accomplished from the front control panel. Similar precautions should be taken with oscilloscope circuits, which employ voltages comparable to those used in transmitting equipment.

Avoid exposure to high concentration of RF radiation. When operating high power RF transmitters or radar equipment, make sure that the beam is not directed at personnel, fuel, or ordnance areas. Hazards involved in RF radiation are discussed in a later section of this chapter.

Use only rubber or insulating hose on airlines for blowing out equipment. Use no more than 10 pounds of pressure to avoid damage to the insulation and injury to personnel. Be sure the air is free from water. Never turn compressed air on yourself or others, since it can cause serious injury.

DEGREE OF SHOCK

The amount of current that may pass through the body without danger depends on the individual and the current quantity, the type, path, and length of contact time.

Body resistance varies from 1,000 to 500,000 ohms for unbroken, dry skin. Resistance is lowered by moisture and is highest with dry skin. Breaks, cuts, or burns may lower body resistance to 200 ohms. A current of 1 milliampere can be felt and will cause a person to avoid it. Five milliamperes is about the highest current safe for the average body. If the palm of the hand makes contact with the conductor, a current of about 12 milliamperes will tend to cause the hand muscles to contract, freezing the body to the conductor. Such a shock may or may not cause serious damage, depending on the contact time and your physical condition, particularly the condition of your heart. A current of only 25 milliamperes has been known to be fatal.

Generally, currents between 100 and 200 milliamperes are lethal. Ventricular fibrillation of the heart occurs when the current through the body approaches 100 milliamperes. Ventricular fibrillation is the uncoordinated actions of the walls of the heart's ventricles. This in turn causes the loss of the pumping action of the heart. Fibrillation is difficult to stop by ordinary means; therefore, it is usually fatal.

If currents of 200 milliamperes or higher pass through the body severe burns and unconsciousness result. Generally, in these cases the heart will not fibrillate but will be stopped. The victim will usually respond if by some means the heart is caused to start again. The heart may respond if resuscitation in the form of artificial respiration is given to the victim.

When a person is rendered unconscious by a current passing through the body, it is impossible to tell how much current caused the unconsciousness. Artificial respiration must be applied immediately if breathing has stopped and continued until otherwise directed by medical authority.

SPECIAL COMPONENTS

In addition to the general hazards and precautions listed previously, several components common to aviation electronic maintenance present hazards or potential hazards. The following paragraphs present a brief summary of some of the more important of these components and their hazards.

Selenium Rectifiers

When selenium rectifiers burn out, fumes of selenium dioxide are liberated, causing an overpowering stench. The fumes are poisonous

13192

Prepared from information supplied by Dr. Merritt R. Nelson, Department of Plant Pathology, University of Arizona.

in Plant Pathology

Note: The information given herein is supplied with the understanding that no discrimination is intended and no indorsement by the Arizona Extension Service is implied.

and should not be breathed. If a rectifier burns out, deenergize the equipment immediately and ventilate the compartment. Allow the damaged rectifier to cool before attempting any repairs. If possible, move the equipment containing it out of doors. Do not touch or handle the defective rectifier while it is hot, since a skin burn might result, permitting some of the selenium compound to be absorbed.

Batteries

Battery hazards are most common during the charging process and during the installation and removal process. The weight and clumsiness of the battery contribue to the strain hazard; commonsense and routine attention to detail minimize this hazard. All rechargeable storage batteries should be charged in strict accordance with the manufacturer's recommendations.

LEAD-ACID.–Lead-acid storage batteries present hazards of acid burn, explosion, and strain. Burns may be prevented by the proper use of eyeshields, rubber gloves, rubber aprons, and rubber boots with nonslip soles. This protective clothing should be worn whenever refilling, checking, transporting, or charging batteries. Explosion may result from accumulation of hydrogen gas during charging operation. Proper ventilation and strict enforcement of the no smoking rules are mandatory.

NICKEL-CADMIUM.–The electrolyte used in nickel-cadmium (NiCad) batteries is potassium hydroxide (KOH), a highly corrosive alkaline solution which should be handled with the same degree of caution as sulfuric acid. If KOH is sprayed on any material, wash it immediately with liberal quantities of water and neutralize the affected area with vinegar or a weak solution of acetic acid.

An extremely violent explosion would occur if KOH were added to a lead-acid battery or if sulfuric acid were added to a NiCad battery. Although there is no valid excuse for such an occurrence, inattention to detail can make it possible. All battery electrolytes should be kept in clearly marked containers and should, if possible, be kept in different storage areas when not in use.

MERCURY CELL.–Under certain conditions, mercury dry cells or batteries may explode. The most common cause of explosion is overloading the battery (with the subsequent heating and ignition of hydrogen gas within the cell). The loading capacity of the battery is decreased as the battery is discharged. When a mercury cell (or any cell within a mercury battery) has discharged to 70 percent of its nominal voltage, the cell or battery should be replaced. Discharged mercury batteries should never be stored; holes should be punched in the steel jacket and the battery discarded.

Cathode-Ray Tubes

Extreme caution should be exercised in handling a cathode-ray tube (CRT). The glass envelope encloses a high vacuum; and because of the large surface area, the envelope is subjected to considerable total force due to atmospheric pressure. (See chapter 5 of this manual for a discussion of total force and pressure.)

The trend toward the use of larger CRT's has increased the hazard of IMPLOSION (collapse of the glass tubes as a result of atmospheric pressure). The tubes are not considered hazardous if handled properly; but if they are struck, scratched, dropped, or handled improperly in any way, they may become an instrument of severe injury or death.

When handling, installing, or removing a CRT, use extreme care to avoid contact between the tube and any sharp or hard object. Wear suitable gloves to protect the hands. Wear goggles to protect the eyes from flying glass particles in the event of implosion. The goggles should provide both side and front protection, and should have clear lenses that can withstand a rigid impact. Insert the tube carefully into the socket, using only moderate pressure. Do not jiggle the tube. Never hold it by the narrow neck. Do not stand directly in front of the face of the tube; accidental implosion may cause the electron gun or other parts to be propelled directly forward with sufficient velocity to cause severe injury. When the tube must be set down, it is important that the face be placed gently on a thick, clean, soft padding.

In addition to the hazard of implosion, rough handling may also result in displacement of the electrodes within the tube and result in

13193

faulty operation or nonoperation of the tube.

The chemical coating material on the face of the tube may be extremely toxic. When disposing of a broken tube, use protective devices and procedures to insure that none of this compound gets on the hands or into the skin.

Before a CRT is discarded, the danger of implosion must be eliminated. Place the defective tube face down in an empty CRT carton, carefully break off the locating pin from the tube base, and (using a small screwdriver, pliers, or a probe) break off the tip of the glass vacuum seal. (See fig. 3-3.) With the vacuum seal broken, pressure inside and outside the tube becomes equalized, and the danger of implosion is removed. However, all other hazards still remain.

Dielectric Materials

The increasing use of microwave energy and the accompanying increase in power levels have given rise to several significant problems. Among the problems which have arisen are those resulting from the use of certain dielectric materials in new environments without previous application experience. In several cases situations have developed in which personnel were exposed to potentially toxic agents as a direct result of the introduction of new substances about which little toxicological information was available.

AT.15

Figure 3-3.— Constuction of cathode-ray tube base.

One example is the use of sulfur hexafluoride (SF_4) as a gas dielectric to increase power handling capability of waveguides. In its pure state, this gas is essentially inert and nontoxic. However, when arc-over occurs in a waveguide filled with the gas, decomposition products constitute a toxic gas hazard. These toxic gases, which include fluorine, may not irritate the skin, are colorless, and cannot be detected by odor. However, they may cause extreme lung irritation and hemorrhaging.

Arcing may take place periodically in the waveguide until the system fails completely, or at least until system performance drops below an acceptable minimum level. If a maintenance technician should open the waveguide while effecting repairs on the system, he may release these highly toxic agents.

When opening a waveguide pressurized with sulfur hexafluoride, personnel should use approved respiratory protective devices. All such work should be accomplished in a well-ventilated space, and the area should be cleared of all toxic hazard before allowing other personnel to enter the area.

As toxicological or other information regarding safety matters becomes available, precautionary measures and protective devices are developed, distributed, and promulgated. Until it has been ascertained that a new material or substance is completely safe, precautionary measures should be used as if definite hazards were known to exist.

RF RADIATION

Electromagnetic radiation is not visible; its presence must be detected and measured by instruments or approximated by theoretical calculations. Radiated beams of high power RF energy present a health and safety hazard. In general, health and safety factors fall into the ordnance, personnel, fuel, and miscellaneous aspects. The establishment of health and safety precautions regarding electromagnetic radiation is a joint responsibility of the Bureau of Medicine and Surgery, the Naval Air Systems Command, and the Naval Ship Systems Command. Publications which may prove valuable for further reference include Radio-Frequency Hazards Manual, NavOrd OP 3565 (a Confidential manual), and Electronics Instal-

13194

lation and Maintenance Book - Test Methods and Practices, NavShips 100,000.103.

The energy striking an object in an electromagnetic field may be reflected, transmitted, or absorbed; only the absorbed energy constitutes a hazard. The hazard resulting from focused concentration of such energy, like any hazard, can be rendered relatively harmless by understanding and precaution.

ORDNANCE HAZARDS

The hazards of electromagnetic radiation to ordnance (HERO) problem has become acute. The number and variety of electrically initiated explosive devices are increasing rapidly. For example, some currently operational weapons contain more than 75 electroexplosive devices. Continuing development efforts are directed toward reducing weight and space requirements, lowering power requirements, assuring positive response, and increasing safety and reliability. However, these goals are not always complementary.

At the same time, the power of communications and radar transmitting equipment is constantly being increased and the frequency spectrum broadened. The radiofrequency spectrum now used by the airborne Navy extends from 10 kHz to about 20,000 MHz. Transmitter power outputs extend to 10 kw at communications frequencies, and peak power outputs extend to approximately 5 megawatts at radar frequencies.

These trends produce situations which are in direct conflict with each other. On the one hand, transmitters and their antennas have only one purpose–to radiate electromagnetic energy. The initiating elements of ordnance devices need only to be supplied with the proper amount of electrical energy for an explosion to take place. Therefore, with many explosive ordnance items, certain precautions are required for safety and to insure reliable performance.

To meet the growing need for new procedures to reduce the hazard to ordnance equipment from RF radiation, the Naval Air Systems Command has sponsored tests which, coordinated with studies made by other agencies, have provided new guidelines and restrictions for handling electrically initiated ordnance equipment.

The basic problem in determining an ordnance system's susceptibility to RF radiation lies in the evaluation of the antennalike couplings that exist between illuminating fields and the electroexplosive devices in the system. RF energy may enter a weapon as a wave radiated through a hole or crack in the weapon skin, or it may be conducted into the weapon by the firing leads or other wires leading into the weapon.

The exact chances of electroexplosive device firing are quite unpredictable, being dependent upon such variables as frequency, field strength, positional and directional orientation, environment, and metallic or personnel contacts with the ordnance or aircraft.

The most susceptible period is during assembly, disassembly, loading, unloading, or testing in electromagnetic fields. The most likely effects of premature actuation are dudding, reduction of the reliability of the device, or propellant ignition. In extreme cases, there is a definite possibility of warhead detonation.

Some specific safety precautions which the technician must observe with respect to these weapons and ordnance devices include the following:

1. Turn off all RF transmitters during weapon handling operations in the area.
2. Observe all local and general safety and HERO restrictions.
3. Maintain radio and radar silence during assembly, disassembly, loading, unloading, or testing operations.
4. Avoid illumination of ordnance devices by high power RF transmitters.

The HERO problem is a complex one. The hazard, and therefore the solution, is a function not only of frequency and field strength, but also of geometrical configuration, orientation, and the antenna characteristics of the weapon or weapon-aircraft and weapon-launcher combinations. In general, the path by which energy is introduced to the electroexplosive devices is not readily defineable.

Development projects are underway in several areas to provide special devices and material which will have general application as HERO remedies. It is expected that some

13195

of these devices, and some developed by other agencies, will be valuable in the design of new weapons as well as modifications for existing weapons. Many possibilities have been and are being explored. These include shielding, filters, RF dissipating attenuators, less sensitive electroexplosive devices, exploding wires, conductive film igniters, spark gap primers, inductive firing devices, and modifications to aircraft armament circuits.

PERSONNEL HAZARDS

Development of RF systems with high power transmitting tubes and high gain antennas has increased the hazard to personnel in the vicinity of these elements. Harmful effects of overexposure to RF radiation are associated with the average power of the absorbed radiation. They are thermal in nature, and are observed as an increase in overall body temperature or as a temperature rise in certain sensitive organs of the body. The only known nonthermal effects on personnel are due to power density values considerably greater than the power densities normally associated with present RF transmitting systems.

The Bureau of Medicine and Surgery has established safe limits based on the power density of the radiation beam and the exposure time of the human body in the radiation field. All areas in which the RF levels exceed the safe limits are considered hazardous. The Naval Ship Systems Command is responsible for determining hazardous shipboard areas and for decreasing the hazard to personnel from RF radiation. Theoretical calculations and power density measurements are used to establish the distances from radar antennas within which it is not biologically safe for personnel to enter. This information is then used to determine if and where hazardous areas exist. All hazardous areas subject to entry by personnel are posted with warning signs, and the ship's intercommunication system is used to warn personnel when the radars are operating.

Personnel Safety Precautions

While every effort must be made to protect personnel from harmful exposure to RF radiation, it is not considered necessary or desirable, in general, that blanket restrictions on antenna radiation be imposed to achieve this end. The existence of such a policy would tend to restrict maintenance and checkout procedures which could otherwise be carried out in safety, provided proper precautions are taken to keep personnel clear of hazardous intensity levels. These precautions include the following:

1. Visual inspection of feed horns, open ends of waveguides, and openings emitting RF electromagnetic energy must not be made unless the equipment is definitely secured for the purpose of such an inspection.
2. Aircraft employing high power radar should be parked, or their antennas should be oriented, so that the beam is directed away from personnel working areas.
3. All personnel must observe RF hazard warning signs which point out the existence of RF radiation hazards in a specific location or area.
4. Those radar antennas which normally rotate are to be rotated continuously while radiating, or trained to a known safe bearing.
5. Nonrotating antennas must be trained and elevated away from inhabited areas, hangars, shop spaces, ships, piers, etc., while radiating.
6. Where a possibility of accidental overexposure might still exist, have a man stationed within view of the antenna (but well out of the beam and in communication with the operator while the antenna is radiating) to warn personnel of the hazard.
7. Radiation hazard warning signs should be available and must be used, not only where they are required to be permanently posted, but also where they may temporarily restrict access to hazardous areas.

FUEL HAZARDS

The increase in radiated RF energy from higher powered communications and radar equipments in recent years has increased the pontential hazard of RF-induced ignition of volatile fuel-air mixtures. This flammable condition is normally present only close to aircraft fuel vents, open fuel inlets, or spilled fuel, or during over-the-wing fueling operations. Ignition of fuel vapors in air has actually occurred; however, the probability of ignition with normal refueling conditions is remote.

131961

Ignition of gasoline vapors caused by RF-induced arcs is rare because ALL the following conditions must exist:

1. A flammable fuel-air mixture must be present within the range of the induced arcing.
2. The arc must contain a sufficient amount of energy to cause ignition.
3. The gap across which the arc occurs must be a certain minimum distance, and must contain a sufficient amount of the flammable mixture to ignite. The possibility of these conditions occurring simultaneously is probably statistically remote; but since the possibility does exist, care must be exercised.

MISCELLANEOUS ASPECTS

The firing of photoflash bulbs, fluorescent lamps, and neon glowlamps by electromagnetic energy from radar sets is a fairly well known phenomenon. Although this type occurrence is normally of little consequence, burns can result. Photographic personnel should be warned of the presence of any high power radar operating in the area and of the hazards involved.

In a similar manner, steel wool may be set afire, or metallic chips may produce sparks when exposed to radiation. With some high power radar sets, steel wool is ignited with a violent explosion. The presence of oil and spilled fuels in the vicinity of aircraft constitutes a serious hazard. This makes good housekeeping procedures essential.

PERSONNEL INJURIES AND SAFETY EDUCATION

The primary purpose of any safety education program is the PREVENTION of personnel injuries or material damage. For any safety program to be effective, all personnel must be aware of the potential hazards present, and they must observe all necessary precautions at all times. This part of the overall safety education program may be best directed by specially qualified personnel in each aspect of safety, or by a safety engineer if one is available.

A second, but vital, aspect of the safety education program is FIRST AID. This part of the program is usually under the direction of Medical Department personnel.

Since a complete training course of this type is quite time consuming, the most immediate requirement is to instill into all personnel a constant awareness of their actions and their surroundings. This awareness, and commonsense, are absolute essentials–without them no safety education program can be effective. The instilling and maintaining of these characteristics is best promoted by co-worker and immediate supervisory personnel.

13197181

CHAPTER 4

PUBLICATIONS, DRAWINGS, AND SCHEMATICS

At the beginning of World War II, the field of airborne electronics was still quite small. With a little study and some experience, the technician could become quite familiar with all the electronics equipment in the type aircraft employed or supported by his unit. The equipments were comparatively simple, similar in operation and physically large enough for ease of inspection and repair. It was possible for the technician to service, maintain, and repair this equipment with perhaps only an occasional reference to a manual or a schematic.

In the present state of the art, however, this practice is no longer possible. Even a mere listing of the electronics equipment carried on some of the more modern aircraft would be quite lengthy. It is impossible for any one person to be thoroughly familiar with all the various types of electronics equipment in present use; but with a good general background of electronic principles and circuit theory, a little study will enable the technician to rapidly familiarize himself with any specific equipment.

The purpose of this chapter is to discuss some of the sources of information available to the technician, how to use these references, and how to locate details on items of information the technician needs in the performance of his duties. Included in this chapter are discussions of publications, both general and specific; drawings and schematics, including illustrations, block diagrams, and wiring and cabling diagrams; charts and tables; and a brief coverage of procedures for the handling of classified materials and information.

PUBLICATIONS

Naval publications are important sources of information for guiding personnel of the naval aeronautic organization. Generally, these publications fall into two broad groups–those dealing with operational and administrative matters, and those dealing with technical and material matters.

The Secretary of Defense approved a reorganization of the Department of the Navy, which was effective 1 May 1966. This reorganization increases the breadth of authority and responsibility of the Chief of Naval Operations under the continuing direction of the Secretary of the Navy.

The Chief of Naval Operations has three major commands under him–BuPers, BuMed, and Chief of Naval Material.

The Chief of Naval Material heads the Naval Material Command which consists of the following six commands:

1. Naval Air Systems Command.
2. Naval Electronic Systems Command.
3. Naval Ship Systems Command.
4. Naval Ordnance Systems Command.
5. Naval Supply Systems Command.
6. Naval Facilities Engineering Command.

Each of the above commands is headed by a Commander; i.e., Commander, Naval Air Systems Command.

Concurrent with the establishment of the Naval Material Command, the following office and bureaus were abolished:

1. Office of Chief of Naval Material.
2. Bureau of Naval Weapons.
3. Bureau of Ships.
4. Bureau of Supplies and Accounts.
5. Bureau of Yards and Docks.

For example, the Naval Air Systems Command is issuing its own directives and incorporating into its directives pertinent material now in BuWeps directives. Therefore, BuWeps directives and instructions will continue to be

13198

13198

used and referred to in training courses for sometime to come even though the Bureau of Naval Weapons has been replaced by the Naval Air Systems Command.

Publications dealing primarily with the operation and maintenance of aircraft and related equipment within the Naval Establishment originating from the Naval Air Systems Command are issued by authority of the Commander, Naval Air Systems Command.

Publications concerned mainly with the training of flight personnel and air operations emanate from the Office of the Deputy Chief of Naval Operations (AIR).

The Naval Air Technical Services Facility functions as the sponsor of both types of publications and controls the initial distribution, distribution lists, printing, and retention of reproducible copy.

The Forms and Publications Supply Office functions as inventory manager for residual stocks of both types of publications, including the supporting distribution system and numerical cataloging.

The basic sources of technical aeronautic information are the technical manuals (formerly called handbooks) issued by the Naval Air Systems Command. Letter publications usually supplement the information contained in aeronautic technical manuals.

Technicians at the E-4 and E-5 levels are primarily concerned with technical publications; therefore, this discussion is directed mainly toward them. However, it includes some coverage of general and administrative type publications of importance to all naval personnel.

Good technical manuals are vital to the maintenance of modern weapons systems. Our Navy's combat readiness depends, to an increasing degree, on the information and knowledge possessed by maintenance personnel. If these men are to maintain increasingly complex weapons systems, incorporating the latest devices and systems, they must be able to obtain the required information from technical manuals.

The Department of Defense, the Department of the Navy, and the Naval Air Systems Command are working together to improve the standardization and quality of aeronautic maintenance manuals. The purpose of the following discussion is to present some detailed information concerning the contents and uses of these manuals.

PUBLICATIONS LISTS

Aeronautic publications originated by the Naval Air Systems Command and distributed by the Naval Air Technical Services Facility are covered by separate lists and indexes as listed below:

1. Navy Stock List of Forms and Publications, NavSup Publication 2002, Cognizance Symbol I, Section VIII, Part C. This stock list contains a numerical listing by code numbers and latest issue date of available aeronautic technical manual type publications. The date indicates the date of the basic book, latest change, or revision.

2. Navy Stock List of Forms and Publications, NavSup Publication 2002, Cognizance Symbol I, Section VIII, Part D. This stock list contains a listing of latest issue dates of aeronautic letter type publications.

NOTE: These stock lists are prepared by the Forms and Publications Supply Office, Byron, Georgia, and distributed to the mailing list maintained by the Naval Air Technical Services Facility, 700 Robbins Avenue, Philadelphia, Pa., 19111.

3. The Naval Aeronautic Publications Index, NavAir 00-500 (Series), is prepared in three volumes. It is prepared and distributed by the Naval Air Technical Services Facility. Parts A and B are issued in March and September, with supplements quarterly; Part C is issued in July and January, with no supplements.

The Equipment Applicability List, NavAir 00-500A, lists aircraft components and related equipment by model, type, and part number in alphabetical and numerical sequence with the applicable publications shown in appropriate columns. The Aircraft Application List, NavAir 00-500B, lists aeronautic manual publications with respect to their application to specific aircraft. It lists technical manuals dealing with electronics, armament, instruments, accessories, powerplants, aircraft, and certain general publications. It does not list letter type publications. The Directives Application List, NavAir 00-500C, lists active letter type publications and technical directives with respect to their applicability to specific aircraft.

13198

13199

NUMBERING SYSTEM FOR MANUALS

Publications issued by the Naval Air Systems Command are designated according to a numbering system based on the type publication and its material content. The system cannot be described fully in this course because of its complex nature and many exceptions.

Coded designations assigned to technical manuals consist of a prefix and an alphanumeric sequence of three or four parts. The example shown below will be used to explain the system for designation of technical manuals:

Prefix

The prefix may consist of the letters NavAir (NA), NavAer (NA), NavWeps (NW), AN, TO, or CO. NavAer and NavWeps publications were issued by the Bureau of Aeronautics and Bureau of Naval Weapons, respectively. All new publications are designated with the NavAir (NA) prefix.

The prefix AN was previously assigned for technical manuals used jointly by the Navy and the Air Force; they were prepared to coordinate military specifications.

TO was the prefix assigned to technical manuals originated by the Air Force.

CO was previously used to designate a technical manual with a Confidential security classification.

These prefixes, while no longer assigned for new material, will remain in effect for existing assignments until superseded.

Part I

Part I consists of numbers to identify the general subject classification with the basic subject to which they pertain. These numbers usually have two digits; however, when an additional classification breakdown is necessary, Part I consists of two digits followed by a letter. An example of this is found in the 02 (Powerplants) series. A typical entry in this series has the number 02B immediately following the prefix NW. In this example, the B identifies the powerplant as a jet propulsion type.

Table 4-1 lists the general subject categories and their numerical equivalent. In some instances, it will be noted that an equipment category has more than one numerical equivalent. In the case of electronics, which carries the codes 08 and 16, the equipment category is in the process of subdivision or change.

Part II

Part II of the publication number consists of numbers (or numbers and letters) and indicates the specific class, group, type, or model and manufacturer of the equipment. The subject breakdowns are listed at the beginning of each separate major division within NavSup Publication 2002, Cognizance Symbol I, Section VIII, Part C.

For aircraft manuals and equipment manuals, this part will be explained in more detail later.

Part III

Part III consists of a number or numbers which designate a specific manual. For airframes and engines, this part designates a specific type manual. For other types of equipment, this part is assigned in numerical sequence and has no direct reference to the type of manual.

Part IV

Part IV pertains only to certain specific classes of manuals (such as the Maintenance Instructions Manuals for aircraft), and designates a particular manual of a set. Numbering is not completely standardized, and may have decimal or even double decimal suffixes. The exact volume desired may be determined from the lists or indexes of publications.

Instructional equipment and training aids	09 & 28
Meteorology (aerology)	50
Ships installations	51

AIRCRAFT MANUALS

Aircraft manuals are prepared by the manufacturer and published for each aircraft model in naval use. The manual for a particular aircraft model consists of a series of individual publications, each dealing with a definite phase of the overall operation or maintenance program. As indicated in the preceding discussion, aircraft manuals fall into the 01 - series category, and manuals pertaining to a particular model may be identified by an alphanumeric designator immediately following the 01 -.

01 - Series Manuals

Aircraft technical manuals are of several different types, some of which are of extreme importance to the maintenance technician in the routine performance of his normal duties. These types are discussed in some detail in this chapter. Manuals of some other types are of limited importance to avionics personnel, and are discussed only briefly.

Using the previous example of manual designation, the aircraft model to which a manual applies may be determined from Part II of the designator. The numbers are coded to indicate the specific manufacturer, and the letters indicate the particular aircraft model.

GENERAL AIRCRAFT MANUALS.–The 01-1 series manuals do not apply to specific aircraft, but present some aspect of construction, operation, maintenance, repair, or inspection applicable to many models of aircraft. Some important examples of this type manual are NavAer 01-1A-505 (Installation Practices: Aircraft Electric and Electronics Wiring); NavWeps 01-1A-509 (Handbook Aircraft Maintenance Cleaning); and NavWeps 01-1A-509 (Handbook Corrosion Control for aircraft).

FLIGHT MANUALS.–Manuals of this class are identified by the number 1 in Part III of the standard nomenclature. For a given model aircraft, the complete flight manual usually comprises the standard NATOPS manual, pocket checklist, and classified supplements. Although this series is of primary interest to the pilot and aircrew, much of the information is of general interest to all personnel concerned in any manner with that aircraft. One section of special interest to avionics personnel is the func-

00SEI 13201

tional operation of the electronics equipment installed.

STRUCTURAL REPAIR.–Structural Repair Manuals (identified by the number 3 in Part III of the standard nomenclature) usually comprise two manuals. The -3-1 manual is for use by organizational and intermediate level maintenance activities, while the -3-2 manual is for use by depot level maintenance activities. These manuals prescribe procedures and methods for making repairs to structural components of the aircraft.

MISCELLANEOUS MANUALS.–Although the contents of most other aircraft manuals are standardized, the numbering system is not. Some typical examples are the Special Weapons Check List, Special Stores, Assembly Procedures (for guided missile and target aircraft), Source Coded Data, Component and Shop Repair Data, etc. Some aircraft have only a few manuals of this type; others have many.

Maintenance Instructions Manual (MIM)

For this type manual, Part III of the standard designator is the number 2. The MIM comprises a variable number of individual publications, each dealing with some portion of the overall maintenance effort for the applicable model aircraft. The MIM (formerly called Handbooks of Maintenance Instructions) provides information concerning the location, function, operation, removal, installation, testing, adjusting, and troubleshooting of components. Maintenance methods recommended are concerned with procedures such as those which can be performed by an operating squadron.

These manuals provide the technician with an invaluable aid in locating equipment components and interconnecting cables in the aircraft, and for inspection purposes as well as troubleshooting

Before attempting any new task on an aircraft, the Maintenance Instructions Manual for that particular aircraft should be consulted. By proper use of this manual, possible damage may be prevented and much time may be saved. Recommended maintenance methods are concerned with procedures which can be accomplished by operating units, and include a Quality Assurance Summary, which indicates the minimum quality control inspection requirements for each maintenance task.

In the past, these manuals were issued as a single complete unit. They were arranged so that the pertinent sections could be removed and kept available in the shop. At present, the separate sections of these manuals are being issued as separate publications under individual identifying numbers. This facilitates procurement, storage, filing, and use of specific parts of the manual by maintenance personnel.

Avionics maintenance personnel are concerned most often with the sections covering electrical and electronic systems, radio and radar, and wiring data.

NUMBER BREAKDOWN.–Part IV of the standard designator for an aircraft Maintenance Instructions Manual indicates the subject content of the manual. This designator may consist of a single number, a number and decimal, or even a number with double decimals, as required to break down the information sufficiently. Due to the differences in operational usage of various models of aircraft, this system cannot be standardized completely. However, the following partial listing is typical for many of the new aircraft:

-2–Airframe Maintenance Instructions Manual
- -0–Maintenance Planning Data (For some models of aircraft, this data is contained in a -100 publication rather than in -2-0.)
- -1.1–General Information and Servicing
- -1.2–Corrosion Control and Decontamination
- -2–Airframe Systems
- -3–Powerplant and Related Systems
- -4–Instrument Systems
- -5–Electrical Systems
- -5.1–Electrical Power Supply System
- -5.2–Lighting System
- -6–Electronic Systems
- -7–Armanent and Related Systems
- -8–Airborne Missile Control Systems
- -9–Systems Integration
- -10–Wiring Diagrams
- -10.1–Wiring Data Diagrams
- -10.2–Wiring Data Repair

Each category may be broken down into single or double decimal subdivisions as the occasion requires.

COTTON ROOTKNOT NEMATODE

Rootknot nematode (Meloidogyne incognita acrita) of cotton is a serious pest in sandy soils throughout many areas of Arizona. Annual losses are estimated to exceed 2% of the total crop or approximately 17,500 bales. Losses in individual fields may be as high as 50%. Both short and long staple varieties are susceptible. Damping-off or soreshin is increased in nematode infested fields.

Detecting cotton plants attacked by rootknot

Stunted plants growing in soils containing 40% or more sand may be infested with rootknot nematode. Excess wilting may occur, especially during the hotter part of the day. Little or no response from irrigation or fertilizer is common. By carefully digging up the plants, the infected roots are found to be retarded. The taproot is frequently missing or greatly reduced and the lateral roots contain numerous galls or knots. The infestations can also be detected by root examination following harvest and at the time of plowing.

Control of the rootknot nematode in cotton

There are three effective and practical means of controlling the cotton rootknot nematode: crop rotation, summer fallow, and soil fumigation. Rotation of cotton with one of the varieties of alfalfa highly resistant to the rootknot nematode, such as African, Moapa, and Sonora for two or more years reduces the rootknot population for the following cotton crop. In addition, this rotation helps maintain soil fertility at a high enough level for good cotton yields. A one-year rotation of small grains grown during the cool months, followed by grain sorghum in the summer will also reduce the rootknot nematode population for the cotton crop the following year. This also adds crop residue to the soil, thereby increasing cotton yield. Weeds and grass must be eliminated as many serve as host plants to the nematode.

Where it is not practical for growers to rotate crops regularly or to practice summer fallow, soil fumigation is a very effective control method on land planted to cotton year after year.

Fig. 1. Numerous knots form on stunted, twisted roots.

MANUAL BREAKDOWN.–The typical volume of the MIM contains six sections as follows:

Section I–Introduction. Provides a general description of the manual, including the scope of coverage, format, and arrangement of the included information. It contains listings of applicable publications and technical directives required by operating activities pertaining to the specific model aircraft or equipment covered in the manual.

Section II–Description and Operation. Includes a physical description of the aircraft or equipment covered by the manual. It includes a detailed listing of components, with separate tables for equipment components, tube and transistor complements, and fuses and circuit breakers. For equipments, this section also incorporates detailed information regarding input and output characteristics and requirements and operating instructions. Also included is a brief discussion on the theory of operation, definition of terms, explanation of terms and symbols, simplified and partial functional diagrams, and built-in test features.

Section III–Organization Maintenance (Line and Hangar). Presents information on testing and operational checks on the various systems or components covered in the manual. It includes such information as a tools and equipment list, manpower requirements, and test procedures (with pertinent notes, warnings, and cautions). In addition, this section includes system troubleshooting charts for installed equipment, and instructions for removal and installation of the equipment.

Sections IV and V–Intermediate Maintenance (Component Repair) (Section V is not always included.) Some manuals combine all functions of maintenance into a single publication; others have various breakdowns. When this level of maintenance is included, the detailed contents parallel those of Section IV, except that the procedures for individual components (rather than the complete unit), are discussed.

Section VI–Diagrams. Contains the complete set of wiring and schematic diagrams for those units covered in the manual.

Illustrated Parts Breakdown (IPB)

The Illustrated Parts Breakdown normally consists of several individual manuals: one for each major functional element of the aircraft, and a final volume which is an index. It is identified by the -4 following the aircraft designation in the standardized publication identification system. It is useful in the procurement, requisitioning, storing, issuing, and identification of new or reclaimed parts.

It can also be used to determine the exact part or item required for replacement in a repair situation. It can also be used as a guide in reassembly of units which have been disassembled for testing, cleaning, or repair.

The separation of the IPB into its separate manuals does not necessarily follow the same order as the MIM breakdown; however, the type information available is consistent for nearly all IPB's.

MANUAL BREAKDOWN.–With the exception of the Index volume, each volume of the IPB follows generally the same format. It is divided into two sections–Introduction and Group Assembly Parts List.

Section I–Introduction. Contains specific detailed instructions for use of the particular IPB and the set to which it belongs.

Section II–Group Assembly Parts List. Provides reference and identification data for the various assemblies and subassemblies within the scope of the manual. For each assembly and subassembly, the data consists of a diagram and table. (See figs. 4-1 and 4-2.) The diagram indicates the location and general appearance of the item and provides clues for assembling.

Inserts A, B, C, and D illustrate items which are furnished as subassemblies of the major item. In the "description" column of the table, note the progressive indentations. The first entry is the complete assembly, and is begun flush at the left. Index numbers 1 through 15 refer to individual items of material which are parts of the assembly, and are indented one space. Index numbers 16 through 30 are bits and pieces of subassembly D and are indented two spaces. Further disassembly would be indicated by additional breakdown of one of

AT.17

Figure 4-2.—IPB, corresponding table.

13205

the subassemblies, and the parts descriptions would be progressively indented in the table.

Note also the system used to identify attaching parts. Index number 9 is a cover, and the attaching parts are indexed as 10 and 11. This shows that these two items are used separately to attach 9 to the assembly. Sometimes a screw, washer, and nut (set) will be listed as a single item having a single index number. In these cases, the individual parts are still identified and described in the table. An example of this is index number 15. In each case, the words "attaching parts" preceded and followed by slant marks are inserted in the table immediately following the item they are used to attach.

The table furnishes the details regarding the bits and pieces which make up the unit. It is divided into five columns.

Column 1 gives the figure and index number. This number is a three-part sequence with hyphens separating the parts. The first part references the volume or major subdivision of the IPB. The second part indicates the number of the figure referenced. The third part indicates the callout number of the specific piece to which the other information pertains. The first entry always indicates the complete subassembly, and does not normally include the third part of the sequence.

Column 2 gives the part number for the specific item. This part number is used in conjunction with the Index volume of the IPB for stock number identification.

Column 3–Description. Provides the item name, manufacturer's code number (identifiable in the vendor's listing included in Section I), specification drawings, additional breakdown reference figures, and other pertinent data.

Column 4–Units Per Assembly. Specifies the total number of a given item in a single assembly.

Column 5–Usable on Code. When a specific item is used on certain aircraft of a given model, and a different item is used on other aircraft of the same model, this column is used. When all models use the same item, this column is left blank. The coding is explained in the Introduction, Section I.

The first figure of each volume is normally of the aircraft, showing the location of the major items of the aircraft. The callout numbers are referenced in the accompanying table, and are crossindexed with the applicable IPB figure number; this table gives no details except the title of the item or assembly. This figure and table are actually included in the Introduction, Section I.

INDEX BREAKDOWN.–The Index volume of the IPB comprises three sections–Introduction, Numerical Index, and Reference Designation INDEX.

Section I–Introduction. Contains details on the contents and arrangement of the volume.

Section II–Numerical Index. Consists of a numerical index containing all items listed in the Group Assembly Parts Lists of the preceding volumes. It is divided into two parts: The first part lists all the contractor part numbers, and the second part lists all the standard and vendor part numbers. Each part of the section is divided into five columns: Part Number, Federal Stock Number, Volume Figure and Index Number, Source Code, and Accountability/Recovery Code.

Section III–Reference Designation Index. Provides a cross reference between the Reference Designation Number assigned to each item of electrical, electronics, or mechanical equipment and the part number for each such item. Reference designation numbers for each of the items of equipment are determined from the applicable section of the MIM.

USING THE IPB.–In order to derive maximum benefit from maintenance functions, certain records and reports must be compiled. The requirements for these vary somewhat in different type squadrons and in different areas. The reports and records required in each activity are determined by the maintenance supervisor as one of his administrative duties. One type report that is universally required is the Unsatisfactory Material/Condition Report (discussed in chapter 2 of this manual). This and other reports and records require details concerning parts that have failed or that have been replaced for any reason. These details are available from the IPB. The procedures for locating the information depends on what is known about the part and what data is required, as shown in the following discussion:

1. When the part number is not known, determine the function and application of the part. Turn to the Table of Contents of the IPB volume

13266

containing the affected equipment or system and select the title that seems most appropriate. Note the illustration page number. Turn to the page indicated and locate the desired part on the illustration. From the illustration, obtain the index (callout) number assigned to the part. Refer to the accompanying description for specific information regarding the part. (If the Federal Stock Number is desired, next refer to the Index volume of the IPB. Locate the part number and note the FSN.)

2. When only the part number is known, refer to the Numerical Index. Locate the part number and note the figure and index number assigned to the part. Turn to the figure indicated, and locate the referenced index number. If a pictorial representation of the part or its location is desired, refer to the same index number on the accompanying illustration. If the FSN is desired, it may be determined directly from the Index volume by locating the part number.

3. When only the reference designation is known, refer to the Reference Designation Index. Locate the reference designation and note the figure and index number and the part number assigned. Turn to the figure indicated and locate the index number. If a pictorial representation of the part, or its location is desired, refer to the index number shown on the accompanying illustration.

Periodic Maintenance Requirements Manual (PMRM)

Periodic maintenance requirements for a particular model aircraft are contained in the -6 series of publications for that model aircraft. The series includes (in addition to the Periodic Maintenance Requirements Manual) the cards and charts used to plan and control the progress of work in scheduled maintenance actions. They provide step by step procedures for performing the minimum inspections required for each type of scheduled maintenance action.

EQUIPMENT MANUALS

Most items of electronics equipment or test equipment commonly used in naval aviation are covered by a manual or a series of manuals. These manuals are usually prepared by the contractor and distributed by the Naval Air Systems Command. Standardization has not progressed to the same extent as it has in the aircraft manuals; however, some generalizations hold true for most manuals of this group.

08 - Series

Manuals of this category usually apply to older equipments which are still in use. (One very important exception is the NAESU Digest, NavAir 08-1-503, discussed later in this chapter.) The 08- series is at present undergoing a complete reorganization and is being combined with the 16- series for electronics equipment. In the issue of the NavSup Publication 2002 used in preparing this course, the 08- entry refers the user to the 16- entry. In the 16- listing, the 08- manuals are listed preceding the 16- manuals.

16- Series

Manuals of this series are identified by a numbering system similar to that used with the aircraft manuals, consisting of a three-part designation following a prefix. The prefix and the Part I serve the same purpose and follow the same rules as outlined in the preceding section. Parts II and III are not completely standardized except for subsections 30 and 35. The subdivisions of the 16- series are listed in table 4-2.

GENERAL.–The 16-1 Series manuals include several publications of many types, the contents of which do not permit inclusion in any other subseries. They include manuals pertaining to general maintenance practices, training manuals, design guidance data, etc. Some of these manuals have been individually referenced in this chapter; some others are referenced in the current indexes of publications.

RADIO AND RADAR.–Manuals of the 5Q and 5S subseries pertain to older equipments and the manuals do not conform to present standardization format. They include miscellaneous operation and maintenance data for radio and radar equipments.

JOINT NOMENCLATURE RADIO EQUIPMENT.–Manuals of this subseries normally appear in the standard format. Part II of the identifying designator specifies the equipment to

132021

Table 4-2. — 16- Series breakdown.

Subseries	Classification
1	General
5Q	Radio
5S	Radar
30	Joint Nomenclature Radio Equipment
35	Joint Nomenclature Radio Components
40	Signal Corps Nomenclature Equipment
45	Commercial British and Navy Radio Equipment
50	Automatic & Semiautomatic Electronic Checkout Equipment
55	Radio, Radar, Electronic, and Spare Parts Lists

which the manual applies; Part III specifies the type manual. Although Part III is not completely standardized, the number refers to the following type manuals:

Operation Instructions
Service Instructions
Overhaul Instructions
Illustrated Parts Breakdown

Many smaller and less complicated equipments combine two or more of these manuals into one volume, but each of the above manuals will be discussed separately in a later section of this chapter.

OTHER SUBSERIES.–Manuals of the 35 subseries are basically the same as those of the 30 subseries, except that they deal with components rather than complete equipments. Manuals of the 40, 45, 50, and 55 subseries cannot be readily identified as to equipment applicability.

Equipment Nomenclature System.

The Joint Communication–Electronic Nomenclature System ("AN" System), formerly known as the Joint Army-Navy Nomenclature System, is designed so that its indicators will tell at a glance many things pertinent to the item. For example, it tells whether the item is a set or a component, and such other information as where it is used, the kind of equipment, and its purpose.

An indicator for a complete set begins with the letters AN. This is followed by a slant bar and a three-letter group. The three letters of the second group give the general nature of the installation, the type of equipment, and the purpose of the equipment, respectively. Following the three-letter group is a number which indicates the specific model of the equipment. An example of the basic designation is AN/ARC-38. As can be seen in table 4-3, the letters following the slant bar mean airborne radio communications.

When the system just described is applied to a unit of the complete set, the designation is formed by replacing the letters AN with a letter-number group which indicates the type and model of the unit in question. For example, a control unit used with the AN/ARC-38 is designated C-1398/ARC-38. The letter C is an indicator letter which in this case means control. The number following C indicates the specific model of control box. Table 4-4 presents commonly used unit indicator letters that are used in the letter-number group.

Operation Instruction Manual

Operation Instruction Manuals cover the operation of specific equipments and the necessary checks and adjustments required for optimum performance. These instructions are written from the equipment operator's viewpoint and do not include all data vital to the maintenance technician.

Service Instruction Manual

The Service Instruction Manual contains information on maintenance and usage of specific equipment. It provides instructions for alining, maintaining, troubleshooting, and repairing the equipment, as well as concise tabular data on fuses, power drain, number of units, etc. Because of the quantity and complexity of the material involved, the manual is divided into several sections.

Section I, Description and Leading Particulars, gives a description of the equipment and the general principles of its operation. Included in the section is information on the interchangeability of components and any special electrical

13208

Table 4-3–Set indicator letters.

First letter (Designed installation classes)	Second letter (Type of equipment)	Third letter (Purpose)
A - Piloted aircraft	A - Invisible light, heat radiation	A - Auxiliary assemblies (not complete operating sets used with or part of two or more sets or sets series)
B - Underwater mobile, submarine	B - Pigeon (do not use)	B - Bombing
C - Air transportable (inactivated, do not use)	C - Carrier	C - Communications (receiving and transmitting
D - Pilotless carrier	D - Radiac	D - Direction finder, reconnaissance, and/or surveillance
F - Fixed ground	E - Nupac	E - Ejection and/or release
G - General ground use	*F - Photographic	G - Fire-control, or searchlight directing
K - Amphibious	G - Telegraph or teletype	H - Recording and/or reproducing (graphic, meteorological and sound)
M - Ground, mobile	I - Interphone and public address	K - Computing
P - Portable	J - Electromechanical or Inertial wire covered	L - Searchlight control (inactivated, use G)
S - Water surface	K - Telemetering	M - Maintenance and/or test assemblies (including tools)
T - Ground, transportable	L - Countermeasures	N - Navigational aids (including altimeters, beacons, compasses, racons, depth, sounding, approach, and landing)
U - General utility	M - Meteorological	P - Reproducing (inactivated, use H)
V - Ground, vehicular	N - Sound in air	Q - Special, or combination of purposes
W - Water surface and underwater combination	P - Radar	R - Receiving, passive detecting
	Q - Sonar and underwater sound	S - Detecting and/or range and bearing, search
	R - Radio	T - Transmitting
	S - Special types, magnetic, etc., or combinations of types	W - Automatic Flight or remote control
	T - Telephone (wire)	X - Identification and recognition
	V - Visual and visible light	
	W - Armament (peculiar to armament, not otherwise covered)	
	X - Facsimile or television	
	Y - Data processing	

*NOTE: Not for U.S. use except for assigning modification letters to previously type-designated items.

13209

Table 4-4.—Unit indicators letters.

Comp Ind	Family Name	Example of use (Not to be construed as limiting the application of the unit indicator)
AB	Supports, antenna	Antenna mounts, mast bases, most sections, towers, etc.
AM	Amplifiers	Power, audio, interphone, radio frequency, video, electronic control, etc.
AS	Antennae, simple and complex	Arrays, parabolic type, masthead, whip or telescopic loop, dipole, reflector, etc.
*AT	Antennae, simple	For new assignments use AS.
BA	Battery, primary type	B batteries, battery packs, etc.
BB	Battery, secondary type	Storage batteries, battery packs, etc.
BZ	Signal devices, audible	Buzzers, gongs, horns, etc.
C	Controls	Control box, remote tuning control, etc.
CA	Commutator assemblies, sonar	Peculiar to sonar equipment.
CB	Capacitor bank	Used as a power supply.
CG	Cable assemblies, R-F	R-F cables, waveguides, transmission lines, etc., with terminals.
CH	Chassis, drawer, door	A framework designed to accept plug-in modules. May include circuitry and/or receptacles. Does not include the plug-in module(s). It is not a storage facility or blank chassis.
CK	Crystal kits	A kit of crystals with holders.
CM	Comparators	Compares two or more input signals.
CN	Compensators	Electrical and/or mechanical compensating regulating or attenuating apparatus.
CP	Computers	A mechanical and/or electronic mathematical calculating device.
CR	Crystals	Crystal in crystal holder.
CU	Couplers	Impedance coupling devices, directional couplers, etc.
CV	Converters (electronic)	Electronic apparatus for changing the phase, frequency, or from "one" medium to "another."
CW	Covers	Cover, bag, roll, cap, radome, nacelle, etc.
CX	Cable assemblies, non-R-F	Non-R-F cables with terminals, test leads, also composite cables of R-F and non-R-F conductors.
CY	Cases and cabinets	Rigid and semirigid structure for enclosing or carrying equipment.
D	Dispensers	Chaff, leaflet, flare, napalm, bomblet, etc.
DA	Load, dummy	R-F and non-R-F test loads.
DT	Detecting heads	Magnetic pickup device, search coil, hydrophone, etc. (see R-F).
DY	Dynamotors	Dynamotor power supply.
E	Hoists	Sonar hoist assembly, etc.
F	Filters	Bandpass, noise, telephone, wave traps, etc.
FN	Furniture	Chairs, desks, tables, etc.
FR	Frequency measuring device	Frequency meters, tuned cavity, etc.
G	Generators, power	Electrical power generators without prime movers, (see PU and PD).
GO	Goniometers	Goniometers of all types.
GP	Ground rods	Ground rods, stakes, etc.

Table 4-4.—Unit indicators letters—Continued.

Comp Ind	Family Name	Example of use (Not to be construed as limiting the application of the unit indicator)
H	Head, hand, and chest sets	Includes earphone.
HC	Crystal holder	Crystal holder less crystal
HD	Environmental apparatus	Heating, cooling, dehumidifying, pressure, vacuum devices, etc.
ID	Indicators, noncathode-ray tube	Calibrated dials and meters, indicating lights, etc. (see IP).
IL	Insulators	Strain, standoff, feed-through, etc.
IM	Intensity measuring devices	Includes SWR gear, field intensity and noise meters, slotted lines, etc.
IP	Indicators, cathode-ray tube	Azimuth, elevation, panoramic, etc.
J	Junction devices	Junction, jack and terminal boxes, etc.
KY	Keying devices	Mechanical, electrical and electronic keyers, coders, interrupters, etc.
LC	Tools, line construction	Includes special apparatus such as cable plows, etc.
LS	Loudspeakers	Separately housed loudspeakers, intercommunication station.
M	Microphones	Radio, telephone, throat, hand, etc.
MA	Magazines	Magnetic tape or wire, etc.
MD	Modulators, demodulators, discriminators	Device for varying amplitude, frequency or phase.
ME	Meters	Multimeters, volt-ohm-milliammeters, vacuum tube voltmeters, power meters, etc.
MF	Magnets or magnetic field generators	Magnetic tape or wire eraser, electromagnet, permanent magnet, etc.
MK	Miscellaneous kits	Maintenance, modification, etc., except tool and crystal (see CK, TK).
ML	Meteorological devices	Barometer, hygrometer, themometer, scales, etc.
MT	Mountings	Mountings, racks, frames, stands, etc.
MX	Miscellaneous	Equipment not otherwise classified, includes subassemblies. Do not use if better indicator is available.
MU	Memory units	Memory units.
O	Oscillators	Master frequency, blocking, multivibrators, etc. (for test oscillators, see SG).
**OA	Miscellaneous groups	Groups not otherwise classified. Do not use if a more specific indicator, such as OD, OE, OG, etc., applies.
**OB	Multiplexer and/or demultiplexer groups	Multiplexer groups, demultiplexer groups, composites thereof.
OC	Ocenographic devices	Bathythemographs, etc.
**OD	Indicator groups	All types.
**OE	Antenna groups	All types.
**OF	Adapter groups	All types.
**OG	Amplifier groups	All types.
**OH	Simulator groups	All types.
**OJ	Consoles and console groups	All types.
**OK	Control groups	All types.
**OL	Data analysis and data processing groups	All types.

13241

Table 4-4.—Unit indicators letters–Continued.

Comp Ind	Family Name	Example of use (Not to be construed as limiting the application of the unit indicator)
**OM	Modulator and/or demodulator groups	Modulator groups, demodulator groups, composites thereof.
**ON	Interconnecting groups	All types.
**OP	Power Supply groups	All types.
**OQ	Test Set groups	All types.
**OR	Receiver groups	All types.
OS	Oscilloscope, test	Test oscilloscopes for general test purposes.
**OT	Transmitter groups	All types.
**OU	Converter groups	All types.
**OV	Generator groups	All types excluding power generating equipment.
**OW	Terminal groups	Telegraph, telephone, radio, etc.
**OX	Coder, decoder, interrogator, transponder groups	All types.
**OY	Radar Set groups	Do not use if a more specific indicator, such as OE, OR, OT, etc., applies.
**OZ	Radio Set groups	Do not use if a more specific indicator, such as OE, OR, OT, etc., applies.
PD	Prime drivers	Gasoline engines, electric motors, synchros, diesel motors, etc.
PF	Fittings, pole	Cable hanger, clamp, protectors, etc.
*PG	Pigeon articles	Container, loft, vest, etc.
*PH	Photograghic articles	Camera, projector, sensitometer, etc.
PL	Plug-in modules	Plug-in modules not otherwise classified. Do not use if more specific indicators, such as AM, R, T, apply.
PP	Power supplies	Nonrotating machine type such as vibrator pack rectifier, thermoelectric, etc.
PT	Plotting equipments	Except meteorological. Boards, maps, transparent maps, plotting table, etc.
PU	Power equipments	Rotating power equipment except dynamotors, motor-generator, etc.
R	Receivers	Receivers, all types except telephone.
RC	Reels	All types (see RL).
RD	Recorder-reproducers	Sound, graphic, tape, wire, film, disc, facsimile, magnetic, mechanical, etc.
RE	Relay assemblies	Electrical, electronic, etc.
RF	Radio frequency component	Composite component of R-F circuits. Do not use if better indicator is available.
RG	Cables, R-F, Bulk	R-F cable, waveguides, transmission lines, etc. without terminals.
RL	Reeling machines	Mechanisms for dispensing and rewinding antenna or field wire, recording wire or tape, etc.,
RO	Recorders	Sound, graphic, tape, wire, film, disc, facsimile, magnetic, mechanical, etc.
RP	Reproducers	Sound, graphic, tape, wire, film, disc, facsimile, magnetic, mechanical etc.
RR	Reflectors	Target, confusion, etc., except antenna reflectors (see AS).

13212

(1) DBCP (sold commercially as Nemagon or Fumazone) may be injected into the soil at the time the seed beds are layed-up or after they are completed, with either two shanks per row, each 6" from center, or with one shank about 2" from center. Always inject 8" to 10" below area of seed placement. Seal all cracks left by injector shanks by reshaping beds with plow sweeps or pull a ringroller or cultipacker behind the toolbar. The soil should be in good tilth, the temperature 60° F. or above and the moisture about 20% of its moisture holding capacity. The nematocides may be mixed with water following recommendations on the label. However, no advantage has been found in this practice. Adjust delivery rate to give 1/2 gallon of technical DBCP per acre (8.6 lbs. technical/acre). Higher rates have not proven economically superior to that quantity recommended.

(2) DBCP can also be added effectively to the pre-plant irrigation water where the total quantity of water does not exceed 5 to 7 acre inches. Since the entire field must be treated, the dosage must be increased to 3/4 gallon of technical/acre.

Meter the material into the irrigation ditch at a point where the material will be thoroughly mixed with the water. If water tubulence is satisfactory there is no advantage in using a centrifugal pump to meter the nematocide. Good mixing results in the material remaining in suspension even though the water must travel long distances before entering the field. When the bottom of the irrigation ditch becomes white during application, it is evidence that the mixing process is inadequate.

For assistance in determining if soil fumigation is necessary, it's recommended that your county agent be consulted. He will also have useful suggestions for the best method of nematocide applications based on the grower's equipment and farming operation.

Prepared from information supplied by Dr. Ed Nigh, Dept. of Plant Pathology, University of Arizona, and Dr. Harold Reynolds, A. R.S., Tempe, Arizona

Table 4-4.—Unit indicators letters—Continued.

Comp Ind	Family Name	Example of use (Not to be construed as limiting the application of the unit indicator)
RT	Receiver and transmitter	Radio and radar transceivers, composite transmitter and receiver, etc.
S	Shelters	House, tent, protective shelter, etc.
SA	Switching devices	Manual, impact, motor driven, pressure operated, etc.
SB	Switchboards	Telephone, fire control, power, panel, etc.
SG	Generators, signal	Test oscillators, noise generators, etc. (see O)
SM	Simulators	Flight, aircraft, target, signal, etc.
SN	Synchronizers	Equipment to coordinate two or more functions.
ST	Straps	Harness, straps, etc.
SU	Optical device	Telescopes, periscopes, projectors, and boresighting scopes.
T	Transmitters	Transmitters, all types, except telephone.
TA	Telephone apparatus	Miscellaneous telephone equipment.
TB	Towed body	Buoy, fish, paravane, target, etc.
TC	Towed cable	Articulated towing strut, faired cable, etc.
TD	Timing devices	Mechanical and electronic timing devices, range device, multiplexers, electronic gates, etc.
TF	Transformers	Transformers when used as separate items.
TG	Positioning devices	Tilt and/or train assemblies.
TH	Telegraph apparatus	Miscellaneous telegraph apparatus.
TK	Tool kits	Miscellaneous tool assemblies.
TL	Tools	All types except line construction (see LC).
TN	Tuning units	Receiver, Transmitter, antenna, tuning units, etc.
TR	Transducers	Magnetic heads, phonopickups, sonar transducers, vibration pickups, etc. (see H, LS, and M).
TS	Test items	Test and measuring equipment not otherwise included; boresighting and alignment equipment.
TT	Teletypewriter and facsimile apparatus	Miscellaneous tape, teletype, facsimile equipment, etc.
TV	Tester, tube	Electronic tube tester.
TW	Tapes and recording wires	Recording tape and wire, splicing, electrical insulating tape, etc.
U	Connectors, audio and power	Unions, plugs, sockets, adapters, etc.
UG	Connectors, R-F	Unions, plugs, sockets, choke couplings, adapters, elbows, flanges, etc.
V	Vehicles	Carts, dollies, trucks, trailers, etc.
VS	Signaling equipment, visual	Flag sets, serial panels, signal lamp equipment, etc.
WD	Cables, two-conductor	Non-R-F wire, cable and cordage in bulk (see RG).
WF	Cables, four-conductor	Non-R-F wire, cable and cordage in bulk (see RG).
WM	Cables, multiple-conductor	Non-R-F wire, cable and cordage in bulk (see RG).
WS	Cables, single-conductor	Non-R-F wire, cable and cordage in bulk (see RG).
WT	Cables, three-conductor	Non-R-F wire, cable and cordage in bulk (see RG).
ZM	Impedance measuring devices	Used for measuring Q, C, L, R, or PF, etc.

*NOTE: Inactivated for U S. use except for assigning modifcation letters to previously type-designated items

**NOTE: Collection of items part of or used with one set or set series.

13213

or mechanical characteristics of the system or components.

Section II, Special Test Equipment and Special Tools, lists all necessary special test equipment and tools (including test racks) which are used for complete bench testing of the system or the components. Any instructions necessary for modifying the test equipment for special use or for the fabrication of a special test harness are also found in this section.

Section III, Preparation for Use and Reshipment, is divided systematically, showing the method by which the equipment should be handled from the time it is received until it is ready for use by the operator. The section contains general information on uncrating and assembling the equipment on the test bench or in the aircraft, removing it from the aircraft, and recrating it for shipment. Detailed descriptions of cable fabrication and the connections of cables to the components are also included. Applicable data on any checks and adjustments required during installation of the equipment is found in this section.

Section IV, Theory of Operation, presents a general description of the equipment first, and this is followed by the detailed explanations of the individual circuits. The general description is usually given from the viewpoint of circuit development (see the discussion later in this chapter concerning drawings and schematics), and block diagrams are used to trace the development path. The function of each unit is explained, as well as its relationship to other units in the equipment.

Section V, Organizational and Operational Maintenance, provides the instructions essential for the maintenance of the equipment by organizational maintenance personnel, and indicates the level of maintenance activities designated to perform it. Included are the preoperational and daily inspections and tests, the bench-test procedures, and the troubleshooting methods to be used by these activities. Each performance procedure in this section includes instructions essential for the proper use of test equipment in diagnosing a trouble within a specific equipment.

Section VI, Field Maintenance, includes the instructions required for servicing the equipment at the field maintenance levels. In addition to alinement and parts removal procedures, information is given for checking component functions by means of performance checks. Also contained in this section are systematic trouble isolation procedures which assist in localizing a defective part or component to a circuit or group of circuits, depending upon the nature of the equipment. Each performance procedure in this section includes instructions essential for the proper use of the test equipment in diagnosing a trouble within a specific equipment.

Section VII, Diagrams, is described later in this chapter, under the heading, "Drawings and Schematics."

Section VIII, Difference Data Sheets, may be added (when required) to provide information on improved or modified models of the original equipment.

Overhaul Instruction Manual

The Overhaul Instruction Manual provides detailed information for overhauling the electronics equipment and/or component. This includes such procedures as disassembly, cleaning, repair, recalibration, testing, and any other steps necessary for complete overhaul. The manual also includes a tabulated list of test equipment recommended for overhaul. It is issued primarily to overhaul activities because the nature of the work described is usually beyond the capacities and facilities of field maintenance activities.

Illustrated Parts Breakdown

The Illustrated Parts Breakdown for equipments is similar in format, purpose, and usage to the IPB for aircraft as previously discussed.

Combined Manuals

Frequently, especially for components and small items of electronics test equipment, two or more of the above manuals are combined into a single publication. In most of these cases, the general material content may be determined from the title, but the arrangement of sections within the manual will vary with the individual publication.

13214

REVISIONS

In an effort to provide maintenance activities with the latest and most accurate information possible, the Naval Air Systems Command has instituted a program of continuous review and frequent revision of technical publications and manuals. These revisions are classed as formal or informal.

FORMAL revisions are printed, and are distributed as a new manual or as a partial replacement on a page-by-page basis. Formal revisions are reflected in the cumulative supplement to the BuSandA publications index. INFORMAL revisions include changes authorized by other means such as messages, notices, letters, or periodicals. They are normally "pen-and-ink" type changes.

Incorporation of Revised Material

When making a pen-and-ink change to any official publication or directive, be sure to record the source of the corrected material or the authority for the change. In this manner, subsequent users of the document will know that the change is official and also where to look for additional details. Eliminating the confusion which results from too much information, some of which may be incorrect, will make the document much more valuable as a tool for maintenance.

When making a substitute page type revision to a manual, be sure to double check that all instructions forwarded with the change copy are complied with. These instructions normally include the removal of certain pages, and substitution of other pages in their place. Be sure that all canceled pages are removed and disposed of in the proper manner, and that all pages not canceled are retained in their proper sequence.

When making a revision of any type to any official document, record the data concerning the number of the change, authority, date of the incorporation of the revision, and the name or initials of the person making the incorporation. In most technical manuals, a special page is included for this purpose.

Reporting of Errors in Manuals

As a part of the program to improve the quality and accuracy of its technical manuals, the Naval Air Systems Command has initiated a program for encouraging users to report errors and discrepancies. At the time of writing, the program applies only to certain specified types of manuals, but it is planned to expand the program to include all technical manuals. The basic reporting document is the Unsatisfactory Material/Condition Report (UR), as described in chapter 2 of this manual.

SPECIFICATIONS

A specification is a minutely detailed description or designation of the characteristics, particulars, values, or tolerances which must be met by a product or process.

The technician is concerned with specifications every time he performs an inspection, calibration, adjustment, operation, or repair on any unit of electronic equipment. In order for the equipment to fulfill its purpose, it must operate in a specified manner–it must meet definite requirements of sensitivity, power output, timing, phase, frequency, signal characteristics, etc. Specifications for a particular unit are found in the operation and inspection manuals and procedures for the applicable aircraft or equipment.

Failure of an item of electronics equipment to meet its specifications will prevent the aircraft from performing at its maximum capability. This condition calls for the removal, adjustment, repair, or calibration of the defective unit. To insure that all equipments are operating within the tolerances allowed in the specifications, operational inspections must be performed at frequent intervals, and in a precise and thorough manner.

Federal Specifications

Federal specifications are prepared under the direction of and promulgated by the Administrator of General Services, and apply to items in general usage by governmental agencies.

13215

Military Specifications

Military specifications cover materials, products, or services used predominantly by military activities, but which may be used by other federal agencies. These specifications are issued and promulgated by the Office of Standardization, Defense Supply Agencies.

Standards

A standard is a reference or a sample set up or established by competent authority to be used as a guide for comparison or evaluation.

The technician is constantly involved with standards. Every time he measures voltages in a circuit, he is comparing the potentials in that particular circuit with the standard volt. Every time he reads a schematic or block diagram, he recognizes the standard symbols used in the drawing. Every time he reads an explanation of the theory of operation for a circuit, he recognizes and understands the meaning of standard terms. When he replaces a defective resistor or capacitor, he installs a standard item.

Standards make possible the rapid, clear, and concise communication of facts, ideas, and information; without standards, modern technology would be impossible.

FEDERAL STANDARDS.–Federal standards are documents that establish engineering and technical limitations for items, materials, processes, methods, designs, and engineering practices. These documents are for general use by governmental agencies.

MILITARY STANDARDS.–Military standards are documents that establish engineering and technical limitations and applications for items, materials, processes, methods, designs, and engineering practices. These documents are intended primarily for use by agencies of the Department of Defense.

INSTRUCTIONS AND NOTICES

The Navy Directives System is used throughout the Navy for the issuance of directive type releases. Some of these prescribe policy, organization and methods, or procedures; others contain general information. The directives system provides a uniform plan for issuing and maintaining directives; conformance is required of all bureaus, offices, activities, and commands of the Navy. Two types of releases are authorized under the plan–Instructions and Notices.

Information pertaining to action of a continuing nature is contained in Instructions. An Instruction has permanent reference value and remains in effect until the originator supersedes or cancels it. Notices contain information pertaining to action of a onetime nature. A Notice does not have permanent reference value and contains provisions for its own cancellation.

For purposes of identification and accurate filing, all directives can be recognized by the originator's authorized abbreviation; the type of release (whether an Instruction or Notice); a subject classification number; and, in the case of Instructions only, a consecutive number. (Because of their temporary nature, the consecutive number is not assigned to Notices.) This information is assigned by the originator and is placed on each page of the release.

The manner of numbering and identifying directives can be better understood by considering a typical identifier:

SECNAV	INST	5215.1A	
(a)	(b)	(c)	(d)

(a) The authorized abbreviation of the originator of the directive.

(b) The type of release (in this case an Instruction).

(c) The subject number of the directive (obtained from the Table of Subject Classification Numbers).

(d) The consecutive number (found only on Instructions). An originator would assign consecutive numbers to those consecutive instructions with the same subject classification number. In the example above, the subject classification number 5215 concerns "Issuance Systems." If the originator, SecNav, issued additional Instructions dealing with issuance systems, they would be assigned the numbers 5215.2, 5215.3, 5215.4, etc. The letter A indicates that this is the first reissue of the same basic directive.

Subject classification numbers are listed in the Table of Subject Classification Numbers

13216

found in SecNav Instruction P5210.11. This table contains a numerical and alphabetical listing of numbers with their related subjects, and has reference value when information or instructions of a particular nature are desired. This Instruction contains all necessary information concerning the use and procedures of the Navy Directives System.

LETTER TYPE TECHNICAL DIRECTIVES (CHANGES AND BULLETINS)

BuWeps Instruction 5215.8 established a system to promote uniformity in technical directives. This system is limited to instructions of a technical nature which are not contained in technical manuals and which cannot be satisfactorily incorporated as revisions to the manuals. NavSup Publication 2002, Cognizance Symbol I, Section VIII, Part D, together with its latest cumulative supplement, provides a checkoff list for all current technical aeronautic letter publications.

A CHANGE is a technical directive containing instructions and directions to accomplish a material change, modification, repositioning, or alteration in the physical appearance of an aircraft or equipment or the installation of different parts in subassemblies, assemblies, or components in aircraft or equipment.

A BULLETIN is a technical directive containing instructions and directions to accomplish inspections, calibrations, tests and adjustments, or additional instructions on standard rework, methods, limitations, and procedures which do not fall within the change definition.

A GENERAL BULLETIN may be used in instances where the instructions and directions apply to a number of different powerplants, airframes, etc.

An INTERIM CHANGE or an INTERIM BULLETIN is a change or bulletin directive in message form which defines the action to be taken to correct a safety or operational condition which embodies risks considered to be in need of immediate correction. Interim directives may or may not contain the final solution to the problem. Interim directives are issued only when the action classification (discussed below) is Immediate or Urgent.

Action Classification

The action classification and compliance requirements for completing the directed action are of major concern and importance. In establishing time limits, the originator has considered the type and seriousness of the deficiency, operational employment and environmental conditions affecting the deficiency, prior to accomplishment of other changes, and special tools or facilities required.

IMMEDIATE ACTION.–This type directive is concerned with problems involving safety, which would probably result in fatal or serious injury to personnel, or destruction of (or extensive damage to) property, unless corrected within extremely narrow time limits. Immediate Action directives involve the immediate discontinued use of the aircraft, engine, or equipment in the operational employment under which the adverse safety condition exists. If continued use will not involve the affected component or system in either normal or emergency situations, compliance may be deferred until (but no later than) the next periodic inspection for aircraft and engines, and no later than 6 months from date of issue for equipments.

URGENT ACTION.–A directive of this type also indicates a problem in safety conditions which could result in personnel injury or property damage unless corrected. The major difference is that time limits are not quite so close as with Immediate Action directives, but are still narrow. Operating restrictions may or may not be imposed. (This classification may also be used for mission capability changes when operational and deployment commitments are considered of overriding importance.)

Interim directives classified Urgent Action require incorporation within 60 days from date of issue in those aircraft, engines, or equipments employed under conditions in which the hazard exists. If continued operation will not involve use of the affected component under either normal or emergency situations, action may be deferred up to 180 days from date of issue.

Formal directives classified Urgent Action require incorporation not later than the next Progressive Aircraft Rework (PAR) period or

13217

overhaul for aircraft and engines, and 18 months from date of issue for equipments.

ROUTINE ACTION.–These directives indicate conditions which, if uncorrected, could eventually result in personnel injury or property damage, or could have an adverse effect on operation, maintenance, or support functions. Although a hazard may exist, the situation is not considered to be critical; therefore, action may be deferred not more than one PAR or overhaul for aircraft and engines, and 18 months from date of issue for equipments.

Noncritical changes requiring the facilities of a Naval Industrial Activity could seriously interfere with operational or deployment commitments. In this event, the change may be deferred by the controlling custodian until the next succeeding PAR or overhaul.

Title

Changes and bulletins are issued under title subjects–Airframe, Powerplant, Avionics, Accessory, Support Equipment, Aviation Armament, Air Crew System, Photographic, Clothing & Survival Equipment, and Propeller.

Numbering

The number is assigned separately for each type directive and for each title subject, in numerical sequence by date of approval (not necessarily the date of issue). Interim changes and bulletings are numbered in sequence along with formal directives; formal directives issued to supersede interims retain the same sequence number.

Occasionally directives require amendment or revision. A REVISION is a completely new edition of an existing publication, and bears the words "Rev. A" or "Rev. B" as appropriate. An AMENDMENT makes a minor change or addition to the basic directive, and is indicated by "Amendment 1" following the basic title.

Some changes are intended to be installed in stages, or by different level maintenance activities. These changes are issued as "Part I" and "Part II" of the basic directive.

Format

Although there are some slight variations in detail, all letter type technical publications conform generally to a standardized format. Only a few of the topics covered in the directive warrant discussion in this course. They are as follows:

1. Publications affected. Lists the publications which should be revised as a result of incorporation of the directive.
2. Application. Identifies the specific aircraft, engines, or equipment to which the directive applies.
3. Supply Data. Presents detailed information concerning all material and supply transactions involved in support of the directed action.
4. Detailed instructions. For the maintenance technician, this is the most important part of the directive. It presents the detailed step by step procedures to be followed in accomplishing the directed action.
5. Identification. Gives instructions for marking the unit upon completion of the action, for easy identification of those units which have undergone modification.
6. Log entry. Indicates the entry, if any, to be made on the applicable logbook.

Obsolescent Types

Many directives which were issued prior to the standardization of the directives system are still effective. These include Aviation Circular Letters, Technical Orders, Technical Notes, Aircraft Changes and Bulletins, Electronic Material Changes, and Electronic Material Bulletins. Although these directives are no longer being issued, those which have not been canceled or superseded are included in the latest edition of the NavSup 2002.

Local Action

Upon receipt of a letter type technical directive, either formal or interim, the directive must be screened by the maintenance activity to determine its applicability to units or aircraft maintained by that activity. If local compliance is required, a local maintenance instruction (discussed in chapter 2) of this manual is prepared to direct compliance by shop personnel. This local instruction provides a ready reference to determine the status of action based on that directive in the activity,

13218

and provides a record of which units have been processed.

PERIODICALS

Many periodicals of interest to the technician are published and issued by naval activities and commands. A few of the most important are discussed in the following paragraphs.

NAESU Digest

Each month the Naval Aviation Engineering Service Unit (NAESU) prepares and publishes the Digest of U.S. Naval Aviation Electronics. The Digest contains information on electrical and electronics equipment relative to operation, maintenance, installation, and supply. This is an excellent source of information dealing with new equipment and new ideas for the older equipment. It gives the latest procedures (developed by NAESU and other activities) for speeding the testing, calibration, and alinement of equipment. In general, it is as the name suggests–a "digest" of all the latest information pertaining to work in electronics. It should be on the "must read" list for all hands, and always available for ready reference.

Approach

Approach, The Naval Aviation Safety Review, is published monthly by the U.S. Naval Aviation Safety Center. It is distributed to naval aeronautical organizations on the basis of one copy for each ten personnel assigned. It presents the most accurate information currently available on the subject of aviation accident prevention. It is an unofficial publication, and its contents are not to be considered as regulations, orders, or directives. It should, however, be read each month by all aviation personnel.

Naval Aviation News

Naval Aviation News is published monthly by the Chief of Naval Operations and the Naval Air Systems Command. Its purpose is to disseminate information on aircraft, aviation training and operations, and other aeronautical matters.

This publication should be read each month by all naval aviation personnel.

All Hands

ALL HANDS, Nav-Pers-0 Series, the Bureau of Naval Personnel Career Publication, is published monthly by the Bureau of Naval Personnel for the information and interest of the naval service as a whole. It is not an official publication in the sense of constituting authority for action based on information contained therein; nor is it a statement of official policy. However, it is an important publication in that it contains information vital to naval personnel.

Distribution of All Hands is automatic to each activity, and is based on one copy for each ten personnel assigned. It should be read every month by all personnel.

Naval Ordnance BULLETIN

The Naval Ordnance BULLETIN is a CONFIDENTIAL magazine issued quarterly by the Naval Ordnance Systems Command. This Bulletin contains information concerning aviation and ordnance projects of special and general interest, including new developments. The information ranges from suggestions which should help in using present equipment to furnishing a background of information on advanced developments and concepts.

DRAWINGS AND SCHEMATICS

Nearly all technical manuals make extensive use of drawings and diagrams. The technician uses these figures in nearly every phase of his work–the location and identification of units and components, troubleshooting, signal and/or circuit tracing, installation, calibration and adjustment, testing, operation, and evaluation. He uses figures in the study of operating principles of circuits and equipments.

No one particular type illustration is suitable for all applications; therefore, many different types are required. Several of the different types are discussed in the following paragraphs. Each type has its own advantages and disadvantages.

NOTE: Blueprint Reading and Sketching, NavPers 10077-C provides many details con-

13219

cerning the construction of illustrations and drawings. Review of that manual should be made prior to continuing the study of this chapter.

ILLUSTRATIONS

Illustrations are commonly used to present visually the idea of a text. To this end, illustrations are used in many forms. A few of these are the photograph, line drawing, shaded sketch, cutaway view, blueprint, etc. Some of the more common illustrations are discussed briefly in this chapter.

Pictorial

Pictorial illustrations normally indicate physical appearance. They may present details concerning the location, size, construction, physical relationships of size and location, or parts arrangement. They appear throughout manuals of all types, and are useful for locating and identifying systems, equipments, components, or parts. They are used in connection with installation, inspection, servicing, operation, adjustment, calibration, troubleshooting, and repair functions.

Pictorial illustrations may be accurately detailed representations, or they may be merely generalized indications, depending on their purpose. They may be photographs, halftone or shaded sketches, or line drawings.

Cutaway View

A cutaway view is an illustration used to show some detail of construction which would be extremely difficult or impossible to show by conventional pictorial views. It is often used in connection with discussions of physical construction and the operation of mechanical devices. It is frequently used in assembly diagrams and in construction details.

Location and Dimension

Location diagrams are used to show physical position relationships, and may or may not be sufficiently detailed to show physical appearance. They are primarily useful for familiarization, and are commonly used in Flight Manuals, in the General Information and Servicing section of the Maintenance Instructions Manuals (MIM's), in the Illustrated Parts Breakdown Manual, (IPB) and in the Operation and Maintenance Instructions for equipments.

Dimension diagrams denote physical size and distance. They are useful in planning the layout of bench stations, making equipment installations, or packing materials for reshipment. They are frequently used in the general information sections of technical manuals, and in those sections devoted to familiarization, installation, and shipment. They are also frequently found in change type technical directives.

Location and/or dimension diagrams may be combined with other type illustrations, thus providing additional details without increasing the number of illustrations.

Assembly Diagrams

Assembly diagrams, as the name implies, provide details of construction which are useful in assembling parts into a unit. They are also useful in explaining the operation of mechanical or electromechanical devices.

BLOCK DIAGRAMS

Block diagrams are not used to show physical shape, size, or location; they are used to present a generalized explanation of overall functional operation. They range from very simple to very complex, depending on the type equipment, the quantity and quality of details to be covered, and the purpose for which the information is included. They are found in nearly all manuals dealing with basic or detailed theory of operation, whether of relatively simple subassemblies or of very large and complex systems. The more complex the equipment, the more probable the need for block diagrams.

Many block diagrams are used in connection with electromechanical devices, as well as with electrical or mechanical systems. Proper use of this type diagram helps increase understanding of functional relationships and operation.

ASSET
13220

Symbols

Since block diagrams are used mainly to provide a general analysis of functional operation, symbols are generally used to represent individual circuits or functional components. In order to make maximum use of block diagrams, it is essential to recognize the symbols, and to understand their meanings and limitations. Appendix II of this manual contains many of the common symbols found on block diagrams. Numerous block diagrams are included in this manual.

Signal Flow

One special type of block diagram is called the signal flow diagram or signal flow chart. It is usually used in connection with overall operation of complicated systems such as fire control computers, ASW systems, aircraft control or power distribution systems, or search or navigation radar systems. It includes all features normally associated with block diagrams, and in addition it includes considerable detail regarding signal paths, signal wave-shape, timing sequence and relationships, magnitudes of potentials or signals, frequencies, etc.

WIRING DIAGRAMS

The wiring diagram presents detailed circuitry information concerning electrical and electronics systems. A master wiring diagram is a single diagram that shows all the wiring in a complete system or in an aircraft. In most cases, this diagram would prove to be too large to be usable; it is normally broken down into logical functional sections, each of which may be further subdivided into circuit diagrams. By breaking a system into individual circuit diagrams, each individual circuit may be presented in greater detail. The increased detail provides for easier circuit tracing, testing, and maintenance.

Wiring diagrams fall into two basic classes–chassis wiring and interconnecting diagrams–each with specific purposes and many variations in appearance (depending on application). Wiring diagrams are not generally used for discussions of theory of operation of specific circuits.

Figure 4-3(A) is an example of one type chassis wiring diagram commonly used. This drawing shows the physical layout of the unit, and all component parts and interconnecting tie points are shown. Each indicated part is identified by reference designation number, thus facilitating use of the IPB to determine values and other data. (The values of resistors, capacitors, or other components are normally not indicated on wiring diagrams.) The polarity of semiconductor diodes and of the polarized capacitor is shown. Since this specific diagram shows physical layout and dimensioning details for mounting holes, it could be used as an assembly drawing and also as an installation drawing.

Figure 4-3 (B) shows the reverse side of the same mounting board, together with the wiring interconnections to other components. Actual positioning of circuit components is not indicated, and wire bundles are represented as single lines with the separate wires entering at an angle. (The angle indicates the direction to follow in tracing the circuit to locate the other end of the wire.)

The wire identification coding on this diagram consists of a three-part designation. The first part is a number representing the color code of the wire in accordance with Military Specification MIL-W-76A. (Many other chassis wiring diagrams designate color coding by abbreviations of the actual colors.) The second is the reference part designation number of the item to which the wire is connected. The last is the designation of the specific terminal to which connection is made.

Figure 4-3 (C), while not a wiring diagram, illustrates a method commonly used to show some functional aspect of sealed or special components.

Figure 4-3 (D) illustrates several methods used to indicate connections at terminal strips. The details of wire identification coding used are discussed below.

Wiring diagrams are normally the major content of the last volume of an MIM set, or the last section of most other maintenance manuals. This volume or section contains wiring diagrams for all electrical and electronic systems of the aircraft. The diagrams are prepared separately for each circuit and provide all data necessary to understand the construction of

Alfalfa Stem Nematode

By Ivan J. Shields
Extension Plant Pathologist

FIGURE 1

Each spring, a number of alfalfa fields in Arizona show damage from the stem nematode. Since it was first reported near Safford about 25 years ago, the stem nematode has been found in many parts of the state. It has never been really serious but heavy infestations of the stem nematode Ditylenchus dipsaci have killed plants and reduced stands in small to large areas of fields. Most alfalfa varieties are susceptible.

CHECK BUDS AND STEMS

Heavily-infested plants will fail to produce stems long enough for harvest. This striking symptom is only exhibited during active growing stages of the plant (Figure 1). The stems will be greatly shortened, thickened and club-like (Figure 2). Crown buds, infested with nematodes, become swollen and distorted, and will break off easily. Alfalfa seedlings will also be affected, especially if seeded into nematode-infested stands.

WHEN TO LOOK

The stem nematode is most active under cool, moist conditions, especially after irrigations. In the lower elevations the nematodes are most active through parts of the winter and early spring; at the higher elevations, they are active in spring and summer. Later in the season the higher temperatures and dry conditions stop nematode activity, so the surviving plants return to normal growth. Many of these weakened plants later succumb to infections by soil-borne fungi and bacteria.

HOW IT SPREADS

Once present in a field, these tiny eel-worms are readily spread to other parts of the field or to other fields. They are easily carried down along the borders in irrigation water. The damage is often greatest next to these borders. Tail water from infested fields can carry the nematodes to new fields. They also may stick to feet of grazing animals or be carried by machinery.

Stem nematodes can live many months in infested alfalfa stems, even after it is cut and thus can be spread over many miles when alfalfa hay is shipped from one part of the state to another.

FIGURE 2

WHAT ARE THE CONTROLS?

1. Prevent stem nematode infestations by avoiding use of tail water from old alfalfa fields.

2. Protect healthy alfalfa by harvesting or grazing infested fields last.

3. Keep alfalfa fields in a rotation with crops other than alfalfa.

4. Plow up infested fields and plant to non-susceptible crops such as cotton, barley, wheat, oats, sorghum, lettuce and beans. Do not replant to alfalfa for at least three years.

5. Plant Lahontan if it is adapted to your area. It is resistant to the stem nematode.

Agricultural Experiment Station, The University of Arizona, Tucson

each circuit, to trace each circuit within the system to make continuity and resistance checks, and to perform specific troubleshooting on inoperative or malfunctioning circuits.

Aircraft Wire Identification Coding

To facilitate maintenance, all aircraft wiring is identified on the wiring diagrams exactly as marked in the aircraft. Identification of each wire is coded by a combination of letters and numbers imprinted on the wire at prescribed intervals along its entire run. Figure 4-4 and the accompanying discussion explain the code used in aircraft wiring installation. Complete details are to be found in the latest revision of MIL-W-5088.

The unit number (shown in dashed outline) is used only in those cases having more than one given unit installed in an identical manner in the same aircraft. The wiring concerned with the first such unit bears the prefix 1, and corresponding wires for the second unit have exactly the same designation except for the prefix 2, etc.

The circuit function letter identifies the basic function of the unit in accordance with table 4-5. Note that circuit function R, S, and T wiring may bear a second letter to designate the functional breakdown of the circuit.

Each wire within a given circuit function group is assigned a separate wire number. Wires that are segmented by the use of splices, plug and receptacle connectors, terminal strip tie points, etc., are given a letter segment designation. Passage through a switch, relay, circuit breaker, etc., requires assignment of a new number.

Wire size numbers are omitted in the case of coaxial cables; they are replaced by a dash and coded designator when part of a thermocouple arrangement.

A suffix is added to designate the phase (or ground) in 3-phase a-c power wiring. In the case of thermocouples the suffix denotes the metal element involved.

Cable Construction

Cable construction diagrams present details concerning the fabrication and construction of cables. These details usually include designation of the type connectors or terminals, the identification of wires for each terminal, method of connecting wire to terminal, potting requirements, length of wires, lacing or sleeving specifications, and any other specifications, or special considerations involved.

AT.19

Figure 4-4.–Example of wire Identification coding.

Cable Routing

Diagrams of major systems generally include an isometric shadow outline of the aircraft showing the approximate location of equipment components, and the physical routing of inter-

13224

connecting cables. A cable, regardless of the number of conductors, is represented on an isometric wiring diagram as a single line; no attempt is made to show individual connections at equipment units or in connection boxes. An isometric type drawing thus shows at a glance a picture of the layout of the entire system.

SCHEMATICS

The major purpose of the schematic diagram is to establish the electrical operation of a particular system. It is not drawn to scale, and it shows none of the actual construction details of the system (such as a physical location within the aircraft, physical layout of components, wire routing, or any other physical detail) not essential to understanding circuit operation.

Schematic drawings differ from block diagrams (discussed earlier) by presenting more detail concerning each circuit. Whereas the block diagram deals with functional units of the system, the schematic diagram indicates each individual part which contributes to the functional operation of the circuit.

NOTE: The National Bureau of Standards is now using in all its publications the term hertz, abbreviated Hz, as the term applied to a unit of frequency, one hertz being one cycle per second. Table 4-6 will give you a quick rundown of a few applications of the term to show you how it works.

Simplified Schematics

In large or complex equipments, a complete schematic drawing may be too large for practical use. For this reason, most technical manuals present partial or simplified schematics for individual circuits or units.

Simplified schematics normally omit parts and connections which are not essential to understanding circuit operation. In studying or troubleshooting equipment, the technician frequently must make his own simplified drawings. In these cases he should include only those items that contribute to the purpose of the drawing, but he should take care to include all such items. In using the schematic drawings throughout this manual (and those in technical manuals, textbooks, and other publications), many techniques for simplifying schematics will become apparent. Special attention should be paid to those techniques found useful by the individual maintenance man–they can be extremely important tools in his work.

Electromechanical Drawings

Electromechanical devices such as synchros, gyros, accelerometers, autotune systems, analog computing elements, etc., are quite common in avionics systems. For a complete understanding of these units, neither an electrical drawing nor a mechanical drawing would be adequate–and confusion could result from the use of two drawings. Therefore a com-

bination type drawing, using some aspects of each component type, is used. These drawings are usually simplified both electrically and mechanically, and only those items essential to the operation are indicated on the drawing.

CHARTS AND TABLES

Charts and tables of many types are used throughout all types of technical publications to present factual data in a clear and concise form. As the terms are used in this discussion, a chart is used to present information in lists, pictures, tables, or diagrams; a table is one type of chart, and is used to present or list information in a very condensed form.

Tables prove valuable in instances when the same general type information is to be presented with respect to numerous items. The corresponding details for the items may be listed in columns, arranged so that reading across will present details regarding a specific item, while reading down will present a comparison of items with respect to a certain detail. One very common and useful table of this type is represented by the IPB listings discussed earlier in this chapter.

SECURITY OF CLASSIFIED MATERIAL

It is important that all personnel in the Naval Establishment be aware of (and comply with) regulations governing the use and safeguarding of classified material and information. The basic policy governing security is established and detailed in the Department of the Navy Security Manual for Classified Material, OpNav Instruction 5510.1 (Series). This manual is to be used as a guide by all naval personnel in the handling of classified material. Many of the electronics equipments installed in modern aircraft (and their applicable technical publications) bear security classification, so it is especially important that all personnel in the avionics ratings become thoroughly familiar with security procedures.

It is the personal responsibility of each individual to safeguard all classified material in his possession so as to prevent loss or compromise. It is also his responsibility to avoid unauthorized disclosure of classified information. Material of a classified nature should not be passed on to any person not having the proper security clearance and the need to know.

In contacts with other persons, do not assume that they have the proper security clearance; be SURE before revealing classified information. In conversations and in writing, avoid compromising security. Do not pass any information to unknown personnel until it is sure that the information is not classified.

Remember that notes jotted down concerning classified material may contain classified information, and must be handled accordingly.

13226

CHAPTER 5

ELEMENTARY PHYSICS

The Navy technician is associated with some very complex machines and equipment. He is expected to understand, operate, service, and maintain these machines and equipment, and to instruct new men so that they can also perform these functions. No matter how complex a machine or item of equipment is, its action can be satisfactorily explained as an application of a few basic principles of physics. In order to understand, maintain, and repair the equipment and machinery necessary to the operation of the ships and aircraft of the fleet, an understanding of these basic principles is essential. There can be no question that the technician who possesses this understanding is better equipped to meet the demands placed upon him in his everyday tasks.

Physics is devoted to finding and defining problems, as well as to searching for their solutions. It not only teaches a person to be curious about the physical world, but also provides a means of satisfying that curiosity. The distinction between physics and other sciences cannot be well defined, because the principles of physics also pertain to the other sciences. Physics is a basic branch of science and deals with matter, motion, force, and energy. It deals with the phenomena which arise because matter moves, exerts force, and possesses energy. It is the foundation for the laws governing these phenomena, as expressed in the study of mechanics, hydraulics, magnetism, electricity, heat, light, sound, and nuclear physics. It is closely associated with chemistry and depends heavily upon mathematics for many of its theories and explanations.

BASIC CONCEPTS

In any study of physics, it soon becomes obvious that specific words and terms have specific meanings which must be mastered from the very start. Without an understanding of the exact meaning of the term, there can be no real understanding of the principles involved in the use of that term. Once the term is correctly understood, however, many principles may be discussed briefly to illustrate or to emphasize the particular aspects of interest. The first part of this chapter is devoted to definitions of some physical terms and a brief general discussion of certain particular principles of vital interest to all technical personnel.

MEASUREMENT

In all branches of science, measurement is a very important consideration. In order to evaluate results, it is often essential to know how much, how far, how many, how often, or in what direction. As scientific investigations become more complex, measurements must become more accurate, and new methods must be developed to measure new things.

Measurements may be classed in three broad categories–magnitude, direction, and time. These categories are broken down into several types, each with its own standard units. Measurements of direction and time have become fairly well standardized and have comparatively few subdivisions. Magnitude, on the other hand, is an extremely complex category with many classes and subdivisions involved.

To illustrate the complexity of the magnitude category, consider only a few common examples of measurement dealing with magnitude: weight, distance, temperature, voltage, size, loudness, brightness, etc.; then consider measurements based on combinations of magnitude: density (weight per unit volume), pressure (force per unit are), thermal expansion (increase in size per degree change in temperature), etc. In addition, measurements combine categories: The flow of liquids is measured in volume per unit of time, speed is measured in distance per unit of time, rotation is measured in revolutions per minute, frequency is expressed in cycles per second, (hertz) and so on indefinitely.

The importance of measurement and the necessity of selecting the proper measurement cannot be overemphasized. Several systems of measurement further complicate matters. For example, distance may be measured in feet or in meters; weight in pounds or in kilograms; capacity in quarts or in liters; temperature in degrees Fahrenheit, centigrade, or Kelvin; density in pounds per cubic foot or in grams per cubic centimeter; angles in degrees or in radians; etc.

In this manual, as in many other texts, specific measurements will be described when and as necessary for clarity.

MATTER AND ENERGY

MATTER may be defined basically as "anything that occupies space and has weight or mass." It exists naturally in three states–solid, liquid, or gas. All matter is composed of small particles called molecules. Matter may be changed or combined by various methods–physical, chemical, or nuclear. Matter has many properties; properties possessed by all forms of matter are called general properties, while those properties possessed only by certain classes of matter are referred to as special properties.

ENERGY may be defined basically as "the capacity for doing work." It may be classified in many ways; but for this discussion, energy will be classified as mechanical, chemical, radiant, heat, light, sound, electrical, or magnetic. Energy is constantly being exchanged from one object to another and from one form to another. Physics is primarily the study of matter and energy in their various forms and of the relationships that exist between them.

Law of Conservation

Matter may be converted from one form to another with no change in the total amount of matter. Energy may also be changed in form with no resultant change in the total quantity of energy. In addition, a third statement has been added within the past half century: "Although the total amount of matter and energy remains constant, matter can be converted into energy or energy into matter." This statement is known as the law of conservation for energy and matter. The basic mathematical equation which shows the relationship between matter and energy is as follows:

$$E = mc^2$$

where E represents the amount of energy, m represents the amount of matter (mass), and c represents the velocity of light.

From the equation it may be seen that the destruction of matter creates energy, and that the creation of matter requires expenditure of energy. From this observation it may be implied that a given quantity of matter is the equivalent of some amount of energy. In common usage it is usually stated that matter "possesses" energy.

General Properties of Matter

Matter in all forms possesses certain properties. In the basic definition it has been stated that matter occupies space and has mass. Those two ideas contain most, if not all, of the general properties of matter.

SPACE.–The amount of space occupied by, or enclosed within, the bounding surfaces of a body is called volume. In the study of physics, this concept must be somewhat modified in order to be completely accurate. As stated previously, matter may appear as a solid, as a liquid, or as a gas–each having special properties. In a later section of this chapter it will be shown that for even a specific substance the volume may vary with changes in circumstances. It will also be shown that

13228
ESSEL

liquids and solids tend to retain their volume when physically moved from one container to another; gases tend to assume the volume of the container.

It will be discussed at some length later that all matter is composed of atoms and molecules. In order to clarify our concept of "occupying space," we must deal with these minute particles of matter, which are in turn composed of still smaller particles separated from each other by empty space (which contains no matter). This idea is used to explain two general properties of matter–impenetrability and porosity.

Two objects cannot occupy the same space at the same time; this is known as the "impenetrability of matter." The actual space occupied by the individual subatomic particles cannot be occupied by any other matter. The impenetrability of matter may, at first glance, seem invalid when a cup of salt is poured into a cup of water–the result is considerably less than two cups of salt water. However, matter has an additional general property called "porosity" which explains this apparent loss of volume: The water simply occupies space between particles of salt. Porosity is present in all material–but to an extremely wide range of degree. Generally, gases are extremely porous, liquids only slightly so; solids vary over a wide range, from the sponge to the steel ball.

WEIGHT.–The concept of weight is also quite complicated and involves two general properties of matter–inertia and gravitational attraction. Before discussing weight, these two general properties and the concepts of motion and force must be discussed.

MOTION may be defined as the "act or process of changing place or position." The "state of motion" refers to the amount and the type of motion possessed by a body at some definite instant (or during some interval) of time. A body at rest is not changing in place or position; it is said to have zero motion, or to be motionless.

The natural tendency of any body at rest is to remain at rest; a moving body tends to continue moving in a straight line with no change in speed or direction. A body which obeys this natural tendency is said to be in uniform motion.

Every object tends to maintain a uniform state of motion. A body at rest never starts to move by itself; a body in motion will maintain its speed and direction unless it is caused to change. In order to cause a body to deviate from its condition of uniform motion, a push or a pull must be exerted on it. This requirement is due to that general property of all matter known as INERTIA.

The greater the tendency of a body to maintain uniform motion, the greater its inertia. To assign a numerical value to the inertia of a body, it is compared with some standard which is assigned the inertia value of 1. The quantitative measure of inertia is called the MASS of the body; therefore, since all matter possesses inertia, all matter must also possess mass.

Any change in the state of motion of a body is known as ACCELERATION, and the cause which produces it is called an accelerating force. Acceleration represents the rate of change in the motion of a body, and may represent either an increase or a decrease in speed and/or a change in direction of motion.

FORCE is the action or effect on a body which tends to change the state of motion of the body acted upon. A force may tend to move a body at rest; it may tend to increase or decrease the speed of a moving body; or it may tend to change the direction of motion. The application of a force to a body does not necessarily result in a change in the state of motion; it may only TEND to cause such a change.

A force is any push or pull which acts on a body. Water in a can exerts a force on the sides and bottom of the can. A tug exerts a push or a pull (force) on a barge. A man leaning against a bulkhead exerts a force on the bulkhead.

In the above examples, a physical object is exerting the force and is in direct contact with the body upon which the force is being exerted. Forces of this type are called contact forces. There are other forces which act through empty space without contact–in some cases without even seeming to have any mass associated with them. The force of gravity exerted on a body by the earth–known as the weight of the body–is an example of a force that acts on a body through empty space and without contact. Such a force is known as an

13229

action-at-a-distance force. Electric and magnetic forces are other examples of these action-at-a-distance forces. The space through which these action-at-a-distance forces are effective is called a force field.

Force is a VECTOR quantity; that is, it has both direction and magnitude. A force is completely described when its magnitude, direction, and point of application are given. In a force vector diagram, the starting point of the line represents the point of application of the force. (The topic of vectors–properties, functions, uses, and methods of calculation–is discussed in detail in Rate Training Manual, Mathematics Vol. 2, NavPers 10071-B.)

Any given body, at any given time, is subjected to many forces. In many cases, all these forces may be combined into a single RESULTANT force, which may then be used to determine the total effect on the body. Combination of all individual forces into a single resultant involves the use of trigonometry, which is also covered in NavPers 10071-B.

Each body of matter in the universe attracts every other body with a force which is proportional to the mass of the bodies and inverse to the square of the distance between them. This force is called the UNIVERSAL FORCE OF GRAVITATIONAL ATTRACTION. Since every body exerts this force on every other body, when considering the forces acting on a single body, it is an almost universal practice to resolve all gravitational forces into a single resultant. At or near the surface of the earth, this becomes a fairly simple process–due to its extremely large mass, the earth exerts such a large gravitational attraction that it is entirely practical to ignore all other such attractions and merely use the earth's gravitational attraction as the resultant.

Although gravitational attraction is exerted by each body on the other, in those cases where there is a great difference in the mass of two bodies, it is usually more convenient to consider the force as being exerted by the larger mass on the smaller mass. Thus, it is commonly stated that the earth exerts a gravitational force of attraction on a body. The gravitational attraction exerted by the earth on a body is called GRAVITY.

The gravitational force exerted by the earth on a body is called the WEIGHT of that body, and is expressed in force units. In the English system, force is expressed in pounds. If a body is attracted by a gravitational force of 160 pounds, the body is said to weigh 160 pounds. The gravitational force between two bodies decreases as the distance between them increases; therefore, a body weighs less a mile above the surface of the ocean than it weighs at sea level; it weighs more a mile below sea level.

Conversion of Mass and Weight

The relationship of mass, weight, and gravity may be expressed mathematically by the formula

$$\text{mass} = \frac{\text{weight}}{\text{acceleration due to gravity}}$$

This relationship is valid for any system of measurement, provided only that all measurements are taken in the same system.

In the English system of measurement, the mass is normally measured in slugs, weight in pounds, and acceleration (due to gravity) in feet per second per second. Therefore, the equation in English terms is

$$m = \frac{w(\text{lb})}{g(\text{ft/sec}^2)}$$

(A slug is frequently defined in terms of force and acceleration: A slug is that mass, which, when acted upon by a force of 1 pound, will be accelerated by 32 ft/sec^2.)

In problems involving the use of mass, it is usually convenient to substitute w/32 for m and the weight of the body for w in the equation. (The 32 comes from the fact that the acceleration due to gravity is 32 ft/sec^2.)

Example 1: If a body has a mass of 5 slugs, its weight (in pounds) at sea level (as measured with a spring balance) may be determined from the formula

$$m = \frac{w}{g}$$

Rearranged to solve for the necessary quantity, this formula becomes

13230
13231

$$w = mg$$

Substituting the numerical values,

$$w = 5 \times 32$$

$$w = 160 \text{ lb}$$

The spring-balance weight of the object is 160 lb at sea level.

Example 2: At an altitude where the acceleration due to gravity is only 31.5 ft/sec^2, what is the weight of the 5-slug mass? By using the same equation and substituting numerical values

$$w = mg$$

$$w = 5 \times 31.5$$

$$w = 157.5 \text{ lb}$$

These examples illustrate how weight varies as a result of a change in the force of gravity due to a change in altitude. The value of 32 feet per second per second usually assigned g is only an approximation used when measurements are made at or near sea level. Altitude affects the weight of an object, but its mass remains constant everywhere.

It is interesting to note that spring weighing machines are not legal for trade in most states of the U.S. A spring scale registers the force necessary to overcome the pull which gravitational force exerts on the object being weighed. This gravitational force varies with the altitude of the object on the earth. A balancing scale, usually called a BALANCE, measures mass rather than weight, although the dial is marked in pounds. On a balance, the object to be weighed is compared with a standard unit of mass. The variation due to altitude is canceled because it affects both the standard unit and the object to be weighed. Therefore, the standard mass serves as an accurate unit of measure for all locations on the surface of the earth.

Density and Specific Gravity

The DENSITY of a substance is its weight per unit volume. A cubic foot of water weighs 62.4 pounds; the density of water is 62.4 pounds per cubic foot. (In the metric system the density of water is 1 gram per cubic centimeter.)

The SPECIFIC GRAVITY (S.G.) of a substance is the ratio of the density of the substance to the density of water–

$$\text{S.G.} = \frac{\text{weight of substance}}{\text{weight of equal volume of water}}$$

Specific gravity is not expressed in units but as a pure number. For example, if a substance has a specific gravity of 4, 1 cubic foot of the substance weighs 4 times as much as a cubic foot of water–62.4 times 4 or 249.6 pounds. In metric units, 1 cubic centimeter of a substance with a specific gravity of 4 weighs 1 times 4 or 4 grams. (Note that in the metric system of units, the specific gravity of a substance has the same numerical value as its density.)

Specific gravity and density are independent of the size of the sample under consideration, and depend only upon the substance of which the sample is made. See table 5-1 for typical values of specific gravity for various substances.

A great deal of ingenuity is often needed to measure the volume of irregularly shaped bodies. Sometimes it is practical to divide a body into a series of regularly shaped parts and then apply the rule that the total volume is equal to the sum of the volumes of all individual parts.

Table 5-1.—Typical values of specific gravity.

Substance	Specific gravity
Aluminum	2.7
Brass	8.6
Copper	8.9

Ice	0.92
Iron	7.8
Lead	11.3
Platinum	21.3
Silver	10.5
Steel	7.8
Mercury	13.6
Ethyl alcohol	0.81
Water	1.00

13230
13231

Figure 5-1 demonstrates another method of measuring the volume of small irregular bodies The volume of water displaced by a body submerged in water is equal to the volume of the body.

A somewhat similar consideration is possible for floating bodies. A floating body displaces its own weight of liquid. This may be proved by filling a container to the brim with liquid, then gently lowering the body to the surface of the liquid and catching the liquid that flows over the brim. Weighing the liquid displaced and the original body will prove the truth of the statement.

Pressure and Total Force

Pressure and force, while closely related topics, are not the same thing. A weight of 10 pounds resting on a table exerts a force of 10 pounds. However, the shape of the weight must be taken into consideration to determine the effect of the weight. If the weight consists of a thin sheet of steel resting on a flat surface, the effect is quite different than if the same sheet of steel were resting on a sharp corner.

Pressure is concerned with the distribution of a force with respect to the area over which that force is distributed. Pressure is defined as the force per unit of area, or $P = F/A$. A flat pan of water with a bottom area of 24 square inches and a total weight of 72 pounds exerts a total force of 72 pounds, or a pressure of 72/24 or 3 pounds per square inch, on the flat table. If the pan is balanced on a block with a surface area of 1 square inch, the pressure is 72/1 or 72 pounds per square inch. An aluminum pan with a thin bottom is suitable for use on a flat surface, but may be damaged if placed on the small block.

This concept explains why a sharp knife cuts more easily than a dull one. The smaller area concentrates the applied force (increases the pressure) and penetrates more easily. For hydraulic applications, the relationship between pressure and force is the basic principle of operation. In enclosed liquids under pressure, the pressure is equal at every point on the surfaces of the enclosing container, and therefore the force on a given surface is dependent on the area. In a system consisting of two cylinders connected by a tube, the force on the pistons is proportional to the area.

Kinetic Energy

Moving bodies possess energy because, by virtue of their mass in motion, they are capable of doing work. The energy of mass in motion is called KINETIC energy, and may be expressed by the equation

$$\text{Kinetic energy} = 1/2\ mv^2$$

where m represents the mass of the body, and v is the velocity of its motion. When the moving

ABSTRACT - This text, the first of three
proposed volumes on Machine Drafting, is
organized into a series of drawing plates to
teach the elements of drafting and drafting
skills along with the making of typical shop
drawings. Brief information is given relative
to instruments and equipment, lines,
lettering and constructions. The eight units
of instruction include: (1) Introduction,
four lessons, (2) Use of Drawing Instruments,
five lessons, (3) Drawing Geometric
Construction, six lessons, (4) Orthographic
Projection, three lessons, (5) Tracing, three
lessons, (6) Dimensioning, four lessons, (7)
Working Drawings, six lessons, and (8)
Sectional Drawings. The lesson plan contains
the lesson objective, related information,
and some times questions or assignments.
Achievement tests for each unit are included.

body is stopped, it loses its kinetic energy. The energy is not destroyed, but is merely converted into other forms of energy, such as heat and POTENTIAL energy. It is important to remember that bodies at rest also possess energy by virtue of their position.

COMPOSITION OF MATTER

Many basic facts concerning the structure and composition of matter are presented in Basic Electricity, NavPers 10086-B, and in Basic Electronics, NavPers 10087-B (in connection with the study of transistors). Study of these basic manuals indicates that all matter is composed of atoms, and that these atoms are, in turn, composed of smaller subatomic particles.

The subatomic particles of major interest in elementary physics are the electron, the proton, and the neutron. They may be considered electrical in nature, with the proton representing a positive charge, the electron representing a negative charge, and the neutron being neutral (neither positive nor negative). Although in general the composition of matter follows a consistent pattern for all atoms, the detailed arrangement of subatomic particles is different for each distinct substance. It is the combination and arrangement of the subatomic particles which imparts the distinguishing chemical and physical characteristics to a substance.

The protons and the neutrons of an atom are closely packed together in a nucleus (core), with the electrons revolving around the nucleus. Atoms are normally considered to be electrically neutral–that is, they normally contain an equal number of electrons and protons; but this condition does not actually prevail under all circumstances. Atoms which contain an equal number of electrons and protons are called balanced atoms; those with an excess or a deficiency of electrons are called "ions."

The proton and the neutron have approximately the same mass, which is approximately 1,836 times the mass of an electron. In any atom, nearly all the mass is contained in the nucleus. It may be assumed that under normal conditions any change in the composition of the atom would involve a change in the number of arrangement of the electrons (due to the smaller mass, they are more easily repositioned). This assumption is generally correct–the most notable exception being in the field of nuclear physics, or nucleonics. In chemistry and in general physics, (including electricity and electronics), it is the electron complement that is of major concern.

ELEMENT

The word element is used to denote any one of about 100 substances which comprise the basic substance of all matter. Two or more elements may combine chemically to form a compound; any combination which does not result in a chemical reaction between the different elements is called a mixture. The atom represents the smallest particle of an element. An atom of any one element differs from an atom of any other element in the number of protons in the nucleus; all atoms of a given element contain the same number of protons. Thus, it may be seen that the number of protons in the nucleus determines the type of matter.

The various elements are frequently tabulated according to the number of protons. The number of protons in the nucleus of the atom is referred to as the atomic number of the element.

Nucleus

The study of the nucleus of the atom, known as nucleonics or nuclear physics, is the subject of extensive modern investigation. Experiments on nuclei usually involve the bombardment of the nucleus of an atom, using various types of nuclear particles. By this method the composition of the nucleus is changed, usually resulting in the release of energy. The change to the nucleus may occur as an increase or a decrease in the number of protons and/or neutrons.

If the number of protons is changed, the atom has become an atom of a different element. This process, called "transmutation," is the process sought by the alchemists of the middle ages in their attempts to change various metals into gold. Scientists of that period believed transmutation could be accomplished by chemical means–hence the impetus given to the development of chemistry.

If, on the other hand, only the number of neutrons in the nucleus is changed, the atom

SESCI
13233

remains an atom of the same element. Although all the atoms of any particular element have the same number of protons (atomic number), atoms of certain elements may contain various numbers of neutrons. Hydrogen (the sole exception to the rule that all atoms are composed of three kinds of subatomic particles) normally contains a single proton and a single electron–and no neutrons. However, some hydrogen atoms do contain a neutron. Such atoms (although they are atoms of hydrogen) are known as deuterium, or "heavy hydrogen." (They are called "heavy" because the addition of the neutron has approximately doubled the weight of the atom. Deuterium figured prominently in the research which led to the development of nuclear energy and the atomic bomb.) The atomic weight of an atom is an indication of the total number of protons and neutrons in the atomic nucleus.

Atoms of the same element but which have different atomic weights are called isotopes. Nearly all elements have several isotopes; some are very common, and some are very rare. A few of the isotopes occuring naturally and most of those produced by nuclear bombardment are radioactive or have unstable nuclei. These unstable isotopes undergo a spontaneous nuclear bombardment which eventually results in either a new element or a different isotope of the same element. The rate of spontaneous radioactive decay is measured by "half-life" which is the time required for one-half of a sample of radioactive material to change (by spontaneous radioactive decay) into a different substance.

Electron Shells

The physical and chemical characteristics of an element are determined by the number and distribution of electrons in the atoms of that element. The electrons are arranged in successive groups of electron shells of rotation around the nucleus; each shell can contain no more than a specific number of electrons, as described in chapter 2 of Basic Electronics, NavPers 10087-B. An INERT element (that is, an element which does not combine chemically with any other element) is a substance in which the outer electron shell of each atom is completely filled. In an element that is not chemically inert, one or more electrons are missing from the outer shell. An atom with only one or two electrons in its outer shell can be made to give up those electrons; an atom whose outer shell needs only one or two electrons to be completely filled can accept electrons from another element which has one or two "extras."

The concept of "needed" or "extra" electrons arises from the basic fact that all atoms have a tendency toward completion (filling) of the outer shell. An atom whose outer shell has only two electrons would have to collect six additional ones (no easy task, from an energy standpoint) in order to have the eight required for a full shell. A much easier way to achieve the same objective is to give up the two electrons in the outer shell and let the full shell next to it serve as the new outer shell. In chemical terminology, this concept is called valence, and is the prime determining factor in predicting chemical combinations.

COMPOUNDS AND MIXTURES

Under certain conditions, two or more elements can be brought together in such a way that they unite chemically to form a COMPOUND. The resulting substance may differ widely from any of its component elements; for example, ordinary drinking water is formed by the chemical union of two gases–hydrogen and oxygen. When a compound is produced, two or more atoms of the combining elements join chemically to form the MOLECULE that is typical of the new compound. The molecule is the smallest unit that exhibits the distinguishing characteristics of a compound.

The combination of sodium and chlorine to form the chemical compound sodium chloride (common table salt) is a typical example of the formation of molecules. Sodium is a highly caustic poisonous metal containing eleven electrons; its outer shell consists of a single electron, which may be considered "extra" (a valence of + 1). Chlorine, a highly poisonous gas with seventeen electrons, "lacks" a single electron (has a valence of -1) to fill its outer shell. When the atom of sodium gives up its extra electron, it becomes a positively charged ion. (It has lost a unit of negative charge.) The chlorine, having taken on this extra unit of negative change (electron) to fill its outer shell, becomes a negative ion. Since opposite electric charges attract, the ions stick together to form a molecule of the compound sodium chloride.

813234

The attracting force which holds the ions together in the molecular form is known as the "valence bond," a term which is frequently encountered in the study of transistors.

Note that in the chemical combination, there has been no change in the nucleus of either atom; the only change has occured in the distribution of electrons between the outer shells of the atoms. Also note that the total number of electrons has not changed–there are still the twenty-eight of the original two atoms–although there has been a slight redistribution. Therefore, the molecule is electrically neutral, and has no resultant electrical charge.

Not all chemical combinations of atoms are on a one-for-one basis. In the case of drinking water, two atoms of hydrogen (valence of + 1) are required to combine with a single atom of oxygen (valence of -2) to form a single molecule of water. Some of the more complex chemical compounds consist of many elements with various numbers of atoms of each. All molecules, like all atoms, are normally considered to be electrically neutral. There are some exceptions to this rule, however, with specific cases of interest being the chemical activity in batteries.

Elements or compounds may be physically combined without necessarily undergoing any chemical change. Grains of finely powered iron and sulfur stirred and shaken together retain their own identity as iron or sulfur. Salt dissolved in water is not a compound; it is merely salt dissolved in water. Each chemical substance retains its chemical identity, even though it may undergo a physical change. This is the typical characteristic of a MIXTURE.

STATES OF MATTER

In their natural condition, forms of matter are classified and grouped in many different ways. One such classification is in accordance to their natural state–solid, liquid, or gas. This classification is important because of the common characteristics possessed by substances in one group which distinguish them from substances in the other groups. However, the usefulness of the classification is limited by the fact that most substances can be made to assume any of the three forms.

In all matter, the molecules are assumed to be in constant motion, and it is the extent of this motion that determines the state of matter. The moving molecular particles in all matter possess kinetic energy of motion. The total of this kinetic energy is considered to be the equivalent of the quantity of heat in a sample of the substance. When heat is added, the energy level is increased, and molecular agitation (motion) is increased. When heat is removed, the energy level decreases, and molecular motion diminishes.

In solids, the motion of the molecules is greatly restricted by the rigidity of the crystalline structure of the material. In liquids, the molecular motion is somewhat less restricted, and the substance as a whole is permitted to "flow." In gases, molecular motion is almost entirely random–the molecules are free to move in any direction and are almost constantly in collision both among themselves and with the surfaces of the container.

This topic and some of its more important implications are discussed in detail under the heading "Heat" in a later section of this chapter.

Solids

The outstanding characteristic of a solid is the tendency to retain its size and shape. Any change in these values require the exchange of energy. The common properties of a solid are cohesion and adhesion, tensile strength, ductility, malleability, hardness, brittleness, and elasticity. Ductility is a measure of the ease with which the material can be drawn into a wire. Malleability refers to the ability of some materials to assume a new shape when pounded. Hardness and brittleness are self-explanatory terms. The remaining properties are discussed in more detail in the following paragraphs.

COHESION AND ADHESION.–Cohesion is the molecular attraction between like particles throughout a body, or the force that holds any substance or body together. Adhesion is the molecular attraction existing between surfaces of bodies in contact, or the force which causes unlike materials to stick together.

Cohesion and adhesion are possessed by different materials in widely varying degree. In general, solid bodies are highly cohesive but only slightly adhesive. Fluids (liquids and gases), on the other hand, are usually quite highly ad-

A[illegible]35

hesive but only slightly cohesive. Generally a material having one of these properties to a high degree will possess the other property to a relatively low degree.

TENSILE STRENGTH.–The cohesion between the molecules of a solid explains the property called tensile strength. This is a measure of the resistance of a solid from being pulled apart. Steel possesses this property to a high degree, and is thus very useful in structural work. When a break does occur, the pieces of the solid cannot be stuck back together because merely pressing them together does not bring the molecules into close enough contact to restore the molecular force of cohesion. However, melting the edges of the break (welding) allows the molecules on both sides of the break to flow together, thus bringing them once again into the close contact required for cohesion.

ELASTICITY.–If a substance will spring back to its original form after being deformed, it has the property of elasticity. This property is desirable in materials to be used as springs. Steel and bronze are examples of materials which exhibit this property.

Elasticity of compression is exhibited to some degree by all solids, liquids, and gases; the closeness of the molecules in solids and liquids makes them hard to compress, but gases are easily compressed because the molecules are farther apart.

Liquids

The outstanding characteristic of a liquid is its tendency to retain its own volume while assuming the shape of its container; thus a liquid is considered almost completely flexible and highly fluid.

Liquids are practically incompressible; applied pressure is transmitted through them instantaneously, equally, and undiminished to all points on the enclosing surfaces. Hydraulic apparatus can be used to increase or to decrease input forces, thus providing an action similar to that of mechanical advantage in mechanical systems. Because of these properties, hydraulic servomechanisms have advantages as well as disadvantages and limitations when compared with other systems.

The fluidity of hydraulic liquids permits the component parts of the system to be placed conveniently at widely separated points when necessary. Hydraulic power units can transmit energy around corners and bends without the use of complicated gears and levers. They operate with a minimum of slack and friction, which are often excessive in mechanical linkages. Uniform action is obtained without vibration, and the operation of the system remains largely unaffected by variations in load. The accumulator (which provides the necessary pressurization of the system to furnish practically instantaneous response) can be pressurized during periods of nonaction, thus eliminating the "buildup time" characteristic of electric servos.

However, the hydraulic hoses which transmit the fluid from unit to unit are bulky and heavy compared to electric wiring. Many of the hydraulic fluids in common usage are messy and constitute safety hazards. They contribute to the danger of slipping, they cause deterioration of the insulation on electric wiring, they conduct electricity and thus increase the hazards of short circuiting, and they are flammable.

Rate Training Manual, Fluid Power, NavPers 16193-A, contains considerable detail on the basic theory of hydraulic systems and units.

Gases

The most notable characteristics of a gas are its tendency to assume not only the shape but also the volume of its containers, and the definite relationship that exists between the volume, pressure, and temperature of a confined gas.

The ability of a gas to assume the shape and volume of its container is the result of its extremely active molecular particles, which are free to move in any direction. Cohesion between molecules of a gas is extremely small, so the molecules tend to separate and distribute themselves uniformly throughout the volume of the container. In an unpressurized container of liquid, pressure is exerted on the bottom and the sides of the container up to the level of the liquid. In a gas, however, the pressure is also exerted against the top surface, and the pressure is equal at all points on the enclosing surfaces.

The relationship of volume, pressure, and temperature of a confined gas are explained by Boyle's law, Charles' law, and the general law for gases.

13236

Many laboratory experiments based on these laws make use of the ideas of "standard pressure" and "standard temperature." These are not natural standards, but are standard values selected for convenience in laboratory usage. Standard values are generally used at the beginning of an experiment, or when a temperature or a pressure is to be held constant. Standard temperature is 0° C, the temperature at which pure ice melts. Standard pressure is the pressure exerted by a column of mercury 760 millimeters high. In many practical uses these standards must be changed to other systems of measurement.

All calculations based on the laws of gases make use of "absolute" temperature and pressure. These topics require a somewhat more detailed explanation.

GAS PRESSURE.–Gas pressure may be indicated in either of two ways–absolute pressure or gage pressure. Since the pressure of an absolute vacuum is zero, any pressure measured with respect to this reference is referred to as "absolute pressure." In the present discussion, this value represents the actual pressure exerted by the confined gas.

At sea level the average atmospheric pressure is approximately 14.7 pounds per square inch (psi). This pressure would, in a mercuirial barometer, support a column of mercury 760 millimeters in height. Thus, normal atmospheric pressure is the standard pressure mentioned previously.

However, the actual pressure at sea level varies considerably; and the pressure at any given altitude may differ from that at sea level. Therefore, it is necessary to take into consideration the actual atmospheric pressure when converting absolute pressure to gage pressure (or vice versa).

When a pressure is expressed as the difference between its absolute value and that of the local atmospheric pressure, the measurement is designated "gage" pressure, and is usually expressed in "pounds per square inch gage" (psig). Gage pressure may be converted to absolute pressure by adding the local atmospheric pressure to the gage pressure.

ABSOLUTE ZERO.–Absolute zero, one of the fundamental constants of physics, is usually expressed in terms of the centigrade scale. Its most predominant use is in the study of the kinetic theory of gases. In accordance with the kinetic theory, if the heat energy of a given gas sample could be progressively reduced, some temperature should be reached at which the motions of the molecules would cease entirely. If accurately determined, this temperature could then be taken as a natural reference, or a true "absolute zero" value.

Experiments with hydrogen (making use of the proven correlation with the volume, temperature, and pressure of gases and by calculations based on this correlation) indicated that if a gas were cooled to -273.16° C (used as -273° for most calculations), all molecular motion would cease and no additional heat could be extracted from the substance. At this point both the volume and the pressure would shrink to zero.

When temperatures are measured with respect to the absolute zero reference, they are said to be expressed in the absolute, or Kelvin, scale. Thus, absolute zero may be expressed either as 0° K or as -273° C.

BOYLE'S LAW.–The English scientist Robert Boyle was among the first to study what he called the "springiness of air." By direct measurement he discovered that when the temperature of an enclosed sample of gas was kept constant and the pressure doubled, the volume was reduced to half the former value; as the applied pressure was decreased, the resulting volume increased. From these observations, he concluded that for a constant temperature the product of the volume and pressure of an enclosed gas remains constant. Boyle's law is normally stated: "The volume of an enclosed dry gas varies inversely with its pressure, provided the temperature remains constant."

In equation form, this relationship may be expressed either

$$V_1P_1 = V_2P_2, \text{ or}$$

$$\frac{V_1}{V_2} = \frac{P_2}{P_1}$$

where V_1 and P_1 are the original volume and pressure, and V_2 and P_2 are the revised volume and pressure.

CHARLES' LAW.–The French scientist Jacques Charles provided much of the founda-

13237

tion for the modern kinetic theory of gases. He found that all gases expand and contract in direct proportion to the change in the absolute temperature, provided the pressure is held constant. Expressed in equation form, this part of the law may be expressed

$$V_1T_2 = V_2T_1, \text{ or}$$

$$\frac{V_1}{V_2} = \frac{T_1}{T_2}$$

where V_1 and V_2 refer to the original and final volumes, and T_1 and T_2 indicate the corresponding absolute temperatures.

Since any change in the temperature of a gas causes a corresponding change in volume, it is reasonable to expect that if a given sample of a gas were heated while confined within a given volume, the pressure should increase. By actual experiment, it was found that the increase in pressure was approximately 1/273 of the 0° C pressure for each 1° C increase. Because of this fact, it is normal practice to state this relationship in terms of absolute temperature. In equation form, this part of the law becomes

$$P_1T_2 = P_2T_1, \text{ or}$$

$$\frac{P_1}{P_2} = \frac{T_1}{T_2}$$

In words, this equation states that with a constant volume, the absolute pressure of a gas varies directly with the absolute temperature.

GENERAL GAS LAW.–The facts concerning gases discussed in the preceding sections are summed up and illustrated in figure 5-2. Boyle's law is expressed in (A) of the figure; while the effects of temperature changes on pressure and volume (Charles' law) are illustrated in (B) and (C), respectively.

By combining Boyle's and Charles' laws, a single expression can be derived which states all the information contained in both. This expression is called the GENERAL GAS EQUATION, a very useful form of which is given by the following equation. (NOTE: The capital P and T signify absolute pressure and temperature, respectively.)

AT.21

Figure 5-2.–The general gas law.

$$\frac{P_1V_1}{T_1} = \frac{P_2V_2}{T_2}$$

It can be seen by examination of figure 5-2 that the three equations are special cases of the general equation. Thus, if the temperature remains constant, T_1 equals T_2 and both can be eliminated from the general formula, which then reduces to the form shown in (A). When the volume remains constant, V_1 equals V_2, thereby reducing the general equation to the form given in (B). Similarly, P_1 is equated to P_2 for constant pressure, and the equation then takes the form given in (C).

The general gas law applies with exactness only to "ideal" gases in which the molecules are assumed to be perfectly elastic. However, it describes the behavior of actual gases with sufficient accuracy for most practical purposes.

MECHANICS

Mechanics is that branch of physics which deals primarily with the ideas of force, mass, and motion. Normally considered the fundamental branch of physics, it deals with matter. Many of its principles and ideas may be seen, measured, and tested. Since all other branches of physics are also concerned (to some extent at least) with force, mass, and motion, a thorough understanding of this section will aid in the understanding of later sections of this chapter.

FORCE, MASS, AND MOTION

Each particle in a body is acted upon by gravitational force. However, in every body there is one point at which a single force, equal to the gravitational force and directed upward, would sustain the body in a condition of rest. This point is known as the CENTER OF GRAVITY, and represents the point at which the entire mass of the body appears to be concentrated. The gravitational effect is measured from the center of gravity. In symmetrical objects of uniform mass, this is the geometrical center. In the case of the earth, the center of gravity is near the center of the earth.

When considering the motion of a body, it is usually convenient to describe the path followed by the center of gravity. The natural tendency of a moving body is to move in a manner so that the center of gravity travels in a straight line. Movement of this type is called LINEAR motion.

Some moving bodies, however, do not move in a straight line, but describe an arc or a circular path. Circular motion falls into two general classes–rotation and revolution.

Since objects come in many different shapes and in order to discuss rotary and revolutionary motion, it becomes necessary to consider the location of the center of gravity with respect to the body. (Refer to figure 5-3 for the following discussion.)

In (A), the center of gravity of a ball coincides with the physical center of the ball. However, in the flat washer (B), the center of gravity does not coincide with any part of the object, but is located at the center of the hollow space inside the ring. In irregularly shaped bodies, the center of gravity may be difficult to locate exactly.

If the body is completely free to rotate, the center of rotation coincides with the center of gravity. On the other hand, the body may be restricted in such a manner that rotation is about some point other than the center of gravity. In this event, the center of gravity revolves around the center of rotation. This condition is illustrated in figure 5-4.

In general usage, the gyro rotor (A) is said to ROTATE about its axis, and the ball (B) is said to REVOLVE about a point at the center of its path.

MASSES IN MOTION

Any change in the speed or direction of motion of a body is known as acceleration and requires the application of some force. The acceleration of a body is directly proportional to the force causing that acceleration; acceleration depends also upon the mass of the body. The greater mass of a lead ball makes it harder to move than a wood ball of the same diameter. The wood ball moves farther with the same push.

These observations point to a connection between force, mass, and acceleration, and indicate that the acceleration of a body is directly proportional to the force exerted on that body and inversely proportional to the mass of that body. In mathematical form, this relationship may be expressed as

AT.22

Figure 5-3.–Center of gravity in various bodies.

AT.23

Figure 5-4.–Center of gravity of rotation.

13239

$$a = \frac{F}{m}$$

or, as it is more commonly stated: Force is equal to the product of the mass and acceleration ($F = ma$).

If the accelerating force is applied to the center of gravity in such a manner as to accelerate the body with no rotation, it is called a TRANSLATIONAL force. A force applied in such a manner as to cause the body to rotate about a point is called a TORQUE force.

Laws of Motion

Among the most important discoveries in theoretical physics are the three fundamental laws of motion attributed to Newton. Although some of these laws have been used in explanations of various topics earlier in this chapter, they are restated and consolidated at this point to clarify and summarize much of the discussion regarding mechanical physics. This restatement and consolidation are also used to introduce additional aspects involving the applications of basic mechanical principles.

1. Every body tends to maintain a state of uniform motion unless a force is applied to change the speed or direction of motion.
2. The acceleration of a body is directly proportional to the magnitude of the applied force and inversely proportional to the mass of the body; acceleration is in the direction of the applied force.
3. For every force applied to a body, the body exerts an equal force in the opposite direction.

Momentum

Every moving body tends to maintain uniform motion. Quantitative measurement of this tendency is proportional to the mass of the body, and also to its velocity.
(Momentum = mass x velocity.) This explains why heavy objects in motion at a given speed are harder to stop than lighter objects, and also why it is easier to stop a given body moving at low speed than it is to stop the same body moving at high speed.

WORK, POWER, AND ENERGY

As defined earlier, energy is the capacity for doing work. In mechanical physics, WORK involves the idea of a mass in motion, and is usually regarded as the product of the applied force and the distance through which the mass is moved (work = force x distance). Thus, if a man raises a weight of 100 pounds to a height of 10 feet he accomplishes 1,000 foot-pounds of work. The amount of work accomplished is the same regardless of the time involved. However, the RATE of doing the work may vary greatly.

The rate of doing work (called POWER) is defined as the work accomplished per unit of time (power = work/time). In the example cited above, if the work is accomplished in 10 seconds, power is being expended at the rate of 100 foot-pounds per second; if it takes 5 minutes (300 seconds), the rate is approximately 3.3 foot-pounds per second.

In the English system of measurements, the unit of mechanical power is called the HORSEPOWER and is the equivalent of 33,000 foot-pounds per minute, or 550 foot-pounds per second. Since energy is readily convertible from one form to another, the work and power measurements based on the conversion of energy must also be readily convertible. As an example, the electrical unit of power is the watt. Electrical energy may be converted into mechanical energy; therefore, electrical power must be convertible into mechanical power. One horsepower is the mechanical equivalent of 746 watts of electrical power, and is capable of doing the same amount of work in the same time.

The accomplishment of work always involves a change in the type of energy, but does not normally change the total quantity of energy. Thus, energy applied to an object may produce work, changing the composition of the energy possessed by the object. When the work stops, energy is no longer being "expended," so energy must once again be converted in form–but not necessarily into its original form.

Efficiency

Provided there is no change in the quantity of matter, energy is convertible with no gain or loss. However, the energy resulting from a given

132401

action may not be in the desired form–it may not even be usable in its resultant form. In all branches of physics, this concept is known as EFFICIENCY.

The energy expended is always greater than the energy recovered. An automobile in motion possesses a quantity of kinetic energy dependent on its mass and velocity. In order to stop the car, this energy must be converted into potential energy. When the car is at rest, its potential energy is considerably less than the kinetic energy it possessed while in motion. The difference, or the "energy lost" is converted into heat by the brakes. The heat serves no useful purpose, so the recovered energy is less than the expended energy–the system is less than 100 percent efficient in converting kinetic to potential energy.

The term efficiency is normally used in connection with work and power considerations to denote the ratio of the input to the output work, power, or energy. It is always expressed as a decimal or as a percent less than unity.

Friction

In mechanical physics, the most common cause for the loss of efficiency is FRICTION. Whenever one object is slid or rolled over another, irregularities in the contacting surfaces interlock and cause an opposition to the force being exerted. Even rubbing two smooth pieces of ice together produces friction, although of a much smaller magnitude than in the case of two rough stones. Friction also exists in the contact of air with all exposed parts of an aircraft in flight, as well as in the brakes of the automobile mentioned above.

When a nail is struck with a hammer, the energy of the hammer is transferred to the nail, and the nail is driven into a board. The depth of penetration depends on the momentum of the hammer, the size and shape of the nail, and the hardness of the wood. The larger or duller the nail and the harder the wood, the greater the friction, and therefore the lower the efficiency and less depth of penetration–but the greater the heating of the nail.

Friction is always present in moving machinery, and accounts in part for the fact that the useful work accomplished by the machine is never as great as the energy applied. Work accomplished in overcoming friction is usually not recoverable. Friction can be minimized by decreasing the number of contacting points, by making the contacting areas as small and as smooth as possible, by the use of bearings, or by the use of lubricants.

There are two kinds of friction–sliding and rolling, with rolling friction usually of lower magnitude. Therefore, most machines are constructed so that rolling friction is present rather than sliding friction. The ball bearing and the roller bearing are used to convert sliding friction to rolling friction. A third type, the common (or friction) bearing, utilizes lubricants applied to surfaces which have been made as smooth as possible. Many new types of machines utilize self-lubricating bearings to minimize friction and thus maximize efficiency.

Mechanical Advantage

The concept of mechanical advantage has proved to be one of the great discoveries of science. It permits an increase in force or distance and represents the basic principle involved in levers, block and tackle systems, screws, hydraulic mechanisms, and other work saving devices. However, in the true sense, these devices do not save work, they merely enable humans to accomplish tasks which might otherwise be beyond their capability. For example, a human would normally be considered incapable of lifting the rear end of a truck in order to change a tire; but with a jack, a block and tackle, or a lever, the job can be made comparatively easy.

Mechanical advantage is usually considered with respect to work. Work represents the application of a force through a distance in order to move an object through a distance. Thus, it may be seen that there are two forces involved, each with an appropriate distance. This is illustrated by the simple lever in figure 5-5.

Assuming perfect efficiency, the work input (F_1D_1) is equal to the work output (F_2D_2). Assuming equal distances D_1 and D_2, a force of 10 pounds must be applied at the source in order to counteract a weight of 10 pounds at the load.

By moving the fulcrum nearer the load, less force is required to balance the same load. This is a mechanical advantage of force. If the force is applied in such a manner as to raise the

AT.24

Figure 5-5.–Mechanical advantage.

load 1 foot, the source must be moved through a distance greater than 1 foot. Thus, mechanical advantage of force represents a mechanical disadvantage of distance. By moving the fulcrum nearer the source, these conditions are reversed.

Since the input work equals the output work (assuming no losses), the mechanical advantage may be stated as a ratio of the force or of the distances. In actual situations, friction results in energy loss and decreased efficiency, thereby requiring an even greater input to accomplish the same work.

A more detailed discussion of mechanical advantages and the characteristics of the six basic mechanical devices (the lever, the screw, the inclined plane or wedge, the block and tackle, the wheel and axle, and the gear) is found in the Rate Training Manual, Basic Machines, NavPers 10624-A.

REVOLVING BODIES

Revolving bodies represent masses in motion; therefore, they possess all the characteristics (and obey all the laws) associated with moving bodies. In addition, since they possess a specific type of motion, they have special properties and factors which must be taken into consideration.

Revolving bodies travel in a constantly changing direction, so they must be constantly subjected to an accelerating force. Momentum tends to produce linear motion, but this is prevented by application of a force which restrains the object. This restraining force prevents the object from continuing in a straight line, and is known as CENTRIPETAL force. According to Newton's third law of motion, the centripetal force must be opposed by an equal force which tends to produce linear motion. This second force is known as CENTRIFUGAL force. The two forces, their relationships, and their effects are illustrated in figure 5-6 and the following explanatory example.

The various forces involved in revolving bodies may be illustrated by use of a ball and string. A slip knot is tied in the center of a 10-foot length of twine so as to shorten the line to 5 feet; a rubber ball is attached to one end of the string. Holding the other end of the line, whirl the ball slowly in a circle. Note that the ball exerts a force against the hand (through the string); and that in order to restrain the ball in its circular path, the hand must exert a force (through the string) on the ball. As the ball is revolved at higher speed, the forces increase, and the ball continues in a circular path. As the rotational velocity of the ball is gradually increased, note the increasing forces.

At some rotational speed, the forces involved become great enough to overcome inertial friction, and the knot slips. At this time, allow the velocity of the rotation to stabilize (stop increasing in rotational velocity, but not slowing down, either), so that the existing conditions may be analyzed. When the knot slips, the ball is temporarily unrestrained and is free to assume linear motion in the direction of travel at that instant (tangent to the circle at the instantaneous position). The ball travels in a straight line until the string reaches its full length;

132421

AT.25

Figure 5-6.–Forces on revolving bodies.

during this time, no force is exerted on or by the hand. As soon as all the slack is taken up, there is a sharp jerk–an accelerating force is exerted in order to change the direction of motion from its linear path into a circular rotation. The ball again assumes rotational motion, but with an increase in radius.

The ball does not make as many revolutions in the same time (rotational velocity is decreased), but it does maintain its former linear velocity. (The kinetic energy and the momentum of the ball have not changed.) Since the change in direction is less abrupt with a large radius than with a small one, less accelerating force is required, and the hand will feel less force. If the ball is then accelerated to the same rotational velocity as immediately prior to the slipping of the knot, the linear velocity of the ball becomes much greater than before; the centripetal and centrifugal forces are much greater, also.

In this example, it has been assumed that the hand is fixed at a point which represents the center of rotation. This assumption, while somewhat erroneous, does not affect the general conclusions. For practical purposes, the two forces are equal at all points along the string at any given time, and the magnitude of each force is equal at all points along the string.

In summarizing the conclusions reached by the above example and explanation, consider the following relationship:

$$\text{force} = \frac{\text{mass x velocity}^2}{\text{radius}}$$

where velocity represents the linear velocity of the ball. This emphasizes that the centripetal and the centrifugal forces are equal in magnitude and opposite in direction. Each force is directly proportional to the mass of the body and inversely proportional to the radius of rotation. Each force is also proportional to the square of the velocity.

In revolving or rotating bodies, all particles of the matter which are not on the axis of rotation are subjected to the forces just described. The statement is true whether the motion is through a complete circle, or merely around a curve: An aircraft tends to skid when changing course; an automobile tends to take curves on two wheels. The sharper the curve (smaller radius) or the higher the velocity, the greater the tendency to skid.

WAVE MOTION

Wave motion and radiated energy may be compared with the wave motion of water. When a pebble is dropped into a calm pool of water, a series of circular waves travel away from the disturbance. These waves radiate in all directions on the surface of the water until they are absorbed or until they are diverted by coming into contact with an obstruction of some sort. Water waves are a succession of crests and troughs; the distance from the crest of one wave to the crest of the next is called the wavelength. A cork floating on the surface of the water bobs up and down with the waves, but moves very little in the direction of wave travel. Water waves are called transverse waves because the motion of the water particles is up and down, or at right angles (transverse) to the direction in which the wave is traveling.

A second form of wave motion, also involving the motion of particles of matter, may be produced by the physical vibration of a body. An example of this type wave is the sound wave which is produced by striking the tine of a tuning fork. When struck, the tuning fork sets up a vibratory motion. As the tine moves in an outward direction, the air immediately in front of the tine is compressed so that its momentary pressure is raised above that at other points in the surrounding medium. Because air is elastic, this disturbance is transmitted progressively in an outward direction as a compression wave.

When the tine returns and moves in the inward direction, the air in front of the tine is rarefied so that its momentary pressure is reduced below that at other points in the surrounding medium. This disturbance is also propagated, but in the form of a rarefaction (expansion) wave, and follows the compression wave through the medium.

The compression and expansion waves are also called longitudinal waves, because the particles of matter which comprise the medium move back and forth longitudinally in the direction of wave travel. Figure 5-7 is a simplified representation of the use of a tuning fork to produce a longitudinal wave. The transverse wave shown below the longitudinal wave is merely a convenient device to indicate the relative density of the particles in the medium, and does not reflect the movement of the particles.

The progress of any wave requiring movement of particles in the transmission medium involves two distinct motions: the wave itself moves forward with constant speed, and simultaneously the particles within the medium vibrate. The period of a vibrating particle is the time (t, in seconds) required for the particle to complete one full vibration or cycle. The frequency (f) is the number of vibrations completed per unit of time and is usually expressed in Hertz. The period is the reciprocal of the frequency ($t = 1/f$). The amplitude of vibration is the maximum variation of particle density from the equilibrium density.

A body vibrating at a definite rate produces a disturbance that moves away as a wave in the surrounding medium. The velocity of this wave is equal to the wavelength divided by the period. Since the period is the reciprocal of the frequency, the velocity may be expressed as

$$v = f\lambda$$

where v is the velocity of propagation of the wave in the given medium, f is the frequency in Hertz, and λ is the wavelength in compatible units of measure. The velocity of propagation may also be described as representing the distance that a wave travels during one period.

Two particles are in phase when they are vibrating with the same frequency, and continually pass through corresponding points of their paths at the same time. For any other condition, the particles are out of phase. Two particles are in phase opposition when they reach their maximum displacements in opposite directions at the same time.

AT.26.

Figure 5-7.–Compression and expansion wave propagation.

A third type of wave, the electromagnetic wave, does not involve moving particles of matter, but rely on electric and magnetic force fields. The waves previously discussed cannot be propagated in the absence of a conducting medium–electromagnetic waves are propagated most efficiently in the absence of matter. In the electromagnetic wave, two components are required–an electric field and a magnetic field. These two fields are mutually perpendicular to each other and to the direction of propagation. In the particle waves, the velocity of propagation varies with the particular medium, and is comparatively very slow; in the electromagnetic wave, the velocity of propagation is the speed of light (approximately 186,300 miles per second). Examples of electromagnetic waves include heat, light, radio waves, X-rays, cosmic radiations, ultraviolet rays, etc.

All three types of wave motion obey certain common laws and have certain common characteristics: All are periodic; that is, they all constantly repeat the same pattern so that each succeeding wave is the same as the previous one. Each wave displays the same relationships of wavelength, frequency, period, velocity of propagation, amplitude, and phase; and each is subject to the same conditions of reflection and refraction. In the electromagnetic wave, the maxima and minima are correlated with field intensity rather than with particle density or displacement as in the case of the other waves. In the longitudinal wave, the density is related to particle density; in the electromagnetic wave, density is related to the strength of the electric and magnetic fields. In the electromagnetic wave, the electric field and the magnetic field are in phase with each other.

A wavelength is the distance measured along the axis of propagation between two corresponding points of equal intensity which are in phase on adjacent waves. This length can be represented by the distance between maximum points on successive waves.

A line drawn from the source to any point on one of the waves is called a RAY, and indicates the path over which the wave progresses. Although rays do not actually exist, they are frequently used in illustrations as a convenient method of denoting wave propagation. A wavefront is a surface on which all points are in phase. Wavefronts near the source are sharply curved, while those at a distance are almost flat; individual rays from a distant source are considered to be parallel.

REFLECTION

Within a uniform medium, a ray travels in a straight line. Only at the boundary of two media or in an area where the density of the medium changes do the rays change their direction. When an advancing wavefront encounters a medium of different characteristics, some of its energy is reflected back into the initial medium, and some is transmitted into the second medium. When a wavefront encounters a medium which it cannot penetrate, the wave is reflected from the surface.

REFLECTED waves are simply those waves that are neither transmitted nor absorbed, but are thrown back from the surface of the medium they encounter. If a ray is directed against a reflecting surface, the ray striking the surface is called the INCIDENT ray, and the one that bounces back is the REFLECTED ray. An imaginary line perpendicular to the reflecting surface at the point of impact of the incident ray is called the NORMAL. The angle between the incident ray and the normal is called the ANGLE OF INCIDENCE; the angle between the reflected ray and the normal is the ANGLE OF REFLECTION. These terms are illustrated in figure 5-8.

AT.27

Figure 5-8.–Terms used to describe the reflection of waves.

13245

If the surface of the medium contacted by the incident ray is smooth and polished (as a mirror), each reflected ray will be thrown back at the same angle as the incident ray. The path of the ray reflected from the surface forms an angle exactly equal to the one formed by its path in reaching the medium. This conforms to the law of reflection which states: The angle of incidence is equal to the angle of reflection.

Diffusion

Reflection from a relatively smooth surface presents few problems. As shown in figure 5-9 (A), rays are reflected from a flat smooth surface in an orderly manner with all rays at the same angle and all rays parallel to each order. This is called regular or specular reflection. It is a different matter, however, with a rough surface. The law of reflection is still valid; but due to the rough surface, the angle of incidence is somewhat different for each ray. The reflected rays scatter in all directions, as shown in figure 5-9 (B). This form of reflection is called irregular or diffused reflection.

Focusing

In addition to reflection from a flat surface and diffusion from a rough one, waves may also be focused by reflection from a curved surface. If the reflecting surface is concave, the parallel rays striking its surface are reflected, as shown in figure 5-10 (A). The normal is perpendicular to the surface; therefore, the normals on a curved surface are not parallel to one another. The rays come together, or converge, at some point called the focal point. The location of the focal point depends on the rate of curvature of the reflecting surface.

Illumination

If a point source of waves is located at the focal point of the concave reflector, the reflected rays are formed into a narrow beam, with all reflected rays parallel to one another.

AT.28

Figure 5-9.–Reflection from a plane surface.
(A) Regular (specular); (B) irregular (diffused).

13246

AT.29

Figure 5-10.–Reflection from a concave surface.
(A) Focusing; (B) illumination.

This condition is illustrated in figure 5-10 (B). In this manner, the intensity is increased (or the area is "illuminated"), because rays that would normally be lost are directed into the beam along with the direct rays.

REFRACTION

The change of direction which occurs when a ray passes from one medium into another of different density is called REFRACTION. It is due to the fact that waves travel at various speeds in different transmission media. Refraction always follows a general rule: When a ray passes from one medium into another of greater density, refraction is toward the normal; when passing into a medium of lesser density, refraction is away from the normal. This is illustrated in figure 5-11.

DOPPLER EFFECT

When there is relative motion between the source of a wave and a detector of that wave, the apparent frequency at the terminal position differs from the frequency at the source. If the distance between the source and the detector is decreasing, more wavefronts are encountered per second than when the distance is constant. This results in an apparent increase in frequency. Conversely, if the separation is increasing, fewer waves are encountered, with an apparent decrease in frequency.

These apparent changes in frequency are called the Doppler effect, and affect the operation of equipment used to detect and measure wave energy. The amount of change in the apparent frequency depends on the relative velocity of the source and detector and on the velocity of propagation of the wave. The Doppler effect is important in dealing with sound wave propagation as applicable to sonar equipment operation, and in dealing with electromagnetic wave propagation as applicable to radar search, target detection, fire control,

AT.30

Figure 5-11.–Refraction of a wave.

13247

navigation, etc. Specific applications of the Doppler effect are not discussed in detail in this chapter.

HEAT

Heat represents a form of energy; therefore, it must be readily exchangeable with or convertible into, other forms of energy. The conversion of mechanical energy into heat through friction has been mentioned previously. When a piece of lead is struck a sharp blow with a hammer, part of the kinetic energy of the hammer is converted into heat. In the core of a transformer, electrical and magnetic energy are exchanged; but due to hysteresis and eddy currents, some of the energy is lost as heat. These are some examples of the unwanted conversions, but there are many instances when the production of heat is desirable. Many devices are used almost exclusively to produce heat.

Regardless of how or why it is produced, heat possesses certain characteristics which make it important to the technician. A knowledge of the nature and behavior of heat may prove helpful in understanding the operation of some types of electronics equipment or in determining the cause of nonoperation or faulty operation of others.

NATURE OF HEAT

There are several theories regarding the nature of heat, none of which satisfactorily explain all the characteristics and properties exhibited by heat. The two theories most commonly included in discussions regarding the nature of heat are the kinetic theory and the radiant energy theory.

In the kinetic theory (mentioned earlier in this chapter), it is assumed that the quantity of heat contained by a body is represented by the total kinetic energy possessed by the molecules of the body.

The radiation theory treats radio waves, heat, and light as the same general form of energy, differing primarily in frequency. Heat is considered as a form of electromagnetic energy involving a specific band of frequencies falling between the radio spectrum and light.

A common method used to produce heat energy is the burning process. Burning is a chemical process in which the fuel unites with oxygen, and a flame is usually produced. The amount of heat liberated per unit mass or per unit volume during complete burning is known as the heat of combustion of a substance. By experiment, scientists have found that each fuel produces a given amount of heat per unit quantity burned.

TRANSFER

There are three methods of heat transfer-conduction, convection, and radiation. In addition to these, a phenomenon called absorption is related to the radiation method.

Conduction

The metal handle of a hot pot may burn the hand; a plastic or wooden handle, however, remains relatively cool even though it is in direct contact with the pot. This phenomenon is due to a property of matter known as thermal conductivity. All materials conduct heat–some very readily, some to an almost negligible extent. When heat is applied to a body, the molecules at the point of application become violently agitated, strike the molecules next to them, and cause increased agitation. The process continues until the heat energy is distributed evenly throughout the material. Aluminum and copper are used for cooking pots because they conduct heat very readily to the food being cooked. Wood and plastic are used as handles because they are very poor conductors of heat. As a general rule metals are the best conductors of heat, although some metals are considerably better than others.

Among solids, there is an extreme range of thermal conductivity. In the original example, the metal handle transmits heat from the pot to the hand, with the possibility of burns. The wooden or plastic handle does not conduct heat very well, so the hand is given some protection. Materials that are extremely poor conductors are called "insulators" and are used to prevent heat transfer. Some examples are the wood handle of soldering irons, the finely spun glass or rock wool insulation in

13248

houses, or the asbestos tape or ribbon wrapping used on steam pipes.

Liquids are generally poorer conductors than metals. In figure 5-12, note that the ice in the bottom of the test tube has not yet melted, although the water at the top is boiling. Water is such a poor conductor that the rate of heating of the water at the top of the tube is not sufficient to cause rapid melting of the ice at the bottom.

Since thermal conduction is a process by which molecular energy is passed on by actual contact, gases are generally even poorer conductors than liquids because the molecules are farther apart and molecular contact is not so pronounced.

Convection

Convection is the process in which heat is transferred by movement of a hot fluid. For example, an electron tube gets hotter and hotter until the air surrounding it begins to move. The motion of the air is upward because heated air expands in volume and is forced upward by the denser cool air surrounding it. The upward motion of the heated air carries the heat away from the hot tube by convection. Transfer of heat by convection may be hastened by using a ventilating fan to move the air surrounding a hot object. The rate of cooling of a hot vacuum tube can also be increased by providing copper fins to conduct heat away from the hot tube. The fins provide large surfaces against which cool air can be blown.

AT.31

Figure 5-12.—Water is a poor conductor of heat.

A convection process may take place in a liquid as well as in a gas. One example is a transformer in an oil bath. The hot oil is less dense (has less weight per unit volume) and rises, while the cool oil falls, is heated, and rises in turn.

When the circulation of gas or liquid is not rapid enough to remove sufficient heat, fans or pumps may be used to accelerate the motion of the cooling material. In some installations, pumps are used to circulate water or oil to help cool large equipment. In airborne installations electric fans and blowers are used to aid convection.

Radiation

Conduction and convection cannot wholly account for some of the phenomena that are associated with heat transfer. For example, heating through convection cannot occur in front of an open fire because the air currents are moving toward the fire. It cannot occur through conduction because the conductivity of the air is very low, and the cooler currents of air moving toward the fire would more than overcome the transfer of heat outward. Therefore, heat must travel across space by some means other than conduction and convection.

The existence of another process of heat transfer is still more evident when the heat from the sun is considered. Since conduction and convection take place only through molecular contact within some medium, heat from the sun must reach the earth by some other method. (Outer space is an almost perfect vacuum.) Radiation is the name given to this third method by which heat travels from one place to another.

The term radiation refers to the continual emission of energy from the surface of all bodies. This energy is known as radiant energy. It is in the form of electromagnetic waves and is identical in nature with light waves, radio waves, and X-rays, except for a difference in wavelength. Sunlight is a form of radiant heat energy which travels great distances through cold, empty space to reach the earth. These electromagnetic heat waves are absorbed when they come in contact with nontransparent bodies.

The net result is that the motion of the molecules in the body is increased, as indicated by an increase in the temperature of the body.

The differences in conduction, convection, and radiation are as follows:

1. Although conduction and convection are extremely slow, radiation takes place with the speed of light. This fact is evident at the time of an eclipse of the sun when the shutting off of the heat from the sun takes place at the same time as the shutting off of the light.

2. Radiant heat may pass through a medium without heating it. For example, the air inside a greenhouse may be much warmer than the glass through which the sun's rays pass.

3. Although conducted or convected heat may travel in roundabout routes, radiant heat always travels in a straight line. For example, radiation can be cut off with a screen placed between the source of heat and the body to be protected.

Absorption

The sun, a fire, and an electric light bulb all radiate energy, but a body need not glow to give off heat. A kettle of hot water or a hot soldering iron radiates heat. If the surface is polished or light in color, less heat is radiated. Bodies which do not reflect are good radiators and good absorbers, and bodies that reflect are poor radiators and poor absorbers. This is the reason white clothing is worn in the summer. A practical example of the control of heat is the Thermos bottle. The flask itself is made of two walls of "silvered" glass with a vacuum between them. The vacuum prevents the loss of heat by conduction and convection and the "silver" coating prevents the loss of heat by radiation.

The silver-colored bronze paint on the "radiators" in heating systems is used only for decoration and decreases the efficiency of heat transfer. The most effective color for heat transfer is dull black; dull black is the ideal absorber and also the best radiator.

MEASUREMENT OF HEAT

A unit of heat must be defined as the heat necessary to produce some agreed-on standard of change. There are three such units in common use as follows:

1. One British thermal unit (Btu) is the quantity of heat necessary to raise the temperature of 1 pound of water 1° F.

2. One gram-calorie (small calorie) is the quantity of heat necessary to raise 1 gram of water 1° C.

3. One kilogram-calorie (large calorie) is the quantity of heat necessary to raise 1 kilogram of water 1° C. (One kilogram-calorie equals 1,000 gram-calories.) The gram-calorie or small calorie is much more widely used than the kilogram-calorie or large calorie. The large calorie is used in relation to food energy and for measuring comparatively large amounts of heat. Throughout this discussion, unless otherwise stated, the term calorie means gram-calorie. For purposes of conversion, one Btu equals 252 gram-calories or 0.252 kilogram-calories.

The terms quantity of heat and temperature are commonly misused. The distinction between them should be understood clearly. For example, suppose that two identical pans, containing different amounts of water of the same temperature, are placed over identical gas burner flames for the same length of time. At the end of that time, the smaller amount of water will have reached a higher temperature. Equal amounts of heat have been supplied, but the increase in temperatures is not equal. As another example, suppose that the water in both pans is at the same temperature, say 80° F, and both are to be heated to the boiling point. It is obvious that more heat must be supplied to the larger amount of water. The temperature rise is the same for both pans, but the quantities of heat necessary are different.

Mechanical Equivalent

Mechanical energy is usually expressed in ergs, joules, or foot-pounds. Energy in the form of heat is expressed in calories or in Btu's. In a precise experiment in which electric energy is converted into heat in a resistance wire immersed in water, the results show that 4.186 joules equals 1 gram-calorie, or that 778 foot-pounds equals 1 Btu. The following equation is used when converting from the English system to the metric system·

$$1 \text{ Btu} = 252 \text{ calories}$$

13250

Specific Heat

One important way in which substances differ from one another is that they require different quantities of heat to produce the same temperature change in a given mass of substance. The specific heat capacity of a substance is the quantity of heat needed, per unit mass, to increase the temperature 1°C. The specific heat of a substance is the ratio of its specific heat capacity to the specific heat capacity of water. Specific heat is expressed as a number which, because it is a ratio, has no units and applies to both the English and the metric systems.

Water has a high specific heat capacity. Large bodies of water on the earth keep the air and the surface of the earth at a fairly constant temperature. A great quantity of heat is required to change the temperature of a large lake or river. Therefore, when the temperature of the air falls below that of such bodies of water, they give off large quantities of heat to the air. This process keeps the atmospheric temperature at the surface of the earth from changing very rapidly.

TEMPERATURE

If an object is hot to the touch, it is said to have a "high" temperature; if it is cold to the touch, it has a "low" temperature. In other words, temperature is used as a measure of the hotness or coldness of an object being described. However, hotness and coldness are only relative. For example, on a cold day, metals seem colder to the touch than nonmetals because they conduct heat away from the body more rapidly. Also, upon leaving a warm room the outside air seems cooler than it really is. Going from the outside cold into a warm room, the room seems warmer than it really is. In other words, the temperature a person feels depends upon the state of his body.

Thermometers

The measurement of temperature is known as THERMOMETRY. Many modern thermometers use liquids in sealed containers. Water was the first liquid used, but because it freezes at 0° C it could not measure temperatures below that point. After much experimentation, scientists decided that the best liquids to use in the construction of thermometers are alcohol and mercury because of the low freezing points of these liquids.

LIQUID THERMOMETERS.–The construction of the common laboratory thermometer gives some idea as to the meaning of a change of 1° in temperature. A bulb is blown at one end of a piece of glass tubing of small bore. The tube and bulb are then filled with the liquid to be used. The temperature of both the liquid and the tube during this process are kept at a point higher than the thermometer will reach in normal usage. The glass tube is then sealed and the thermometer is allowed to cool. During the cooling process, the liquid falls away from the top of the tube and creates a vacuum within the thermometer.

For marking, the thermometer is placed in melting ice. The height of the liquid column is marked as the 0°C. point. Next, the thermometer is placed in steam at a pressure of 76 centimeters of mercury and a mark is made at that point to which the liquid inside rises. That is the boiling point or the 100° C, mark. The space between these two marks is then divided into 100 equal parts. These spacings are known as DEGREES. It is this type of thermometer that is used almost exclusively in laboratory work and in testing electrical equipment. It is known as the CENTIGRADE thermometer.

NOTE: Centigrade scale or thermometer may be referred to as Celsius after the inventor.

In English-speaking countries, the FAHRENHEIT thermometer is commonly used for other than physical or chemical laboratory purposes. The freezing point is marked 32° and the boiling point is marked 212°. The space between these marks is divided into 180 equal parts. These divisions are degrees Fahrenheit, named after the scientist who made the first thermometer of this type. In the U.S., weather reports and room temperatures are given in degrees Fahrenheit.

TEMPERATURE CONVERSION.–There are two systems of temperature measurement; it is frequently necessary to convert from one to the other. The range on the centigrade thermometer from the freezing point to the boiling point is 100° C, and the same range on the Fahrenheit thermometer is 180° F. Thus, over the same

temperature range, the liquid moves 180 divisions on the Fahrenheit scale for every 100 divisions on the centigrade scale. A change of 5 on the centigrade scale, therefore, is equal to a change of 9° on the Fahrenheit scale. (The ratio 100/180 reduces to 5/9.) Because zero on the centigrade scale corresponds to 32° on the Fahrenheit scale, a difference in reference points exists between the two scales. (See fig. 5-13.)

To convert from the Fahrenheit scale to the centigrade scale, subtract the 32° difference and multiply the result by 5/9. As an example, convert 68° Fahrenheit to centigrade–

$$\frac{5}{9}(68 - 32)$$

$$\frac{5}{9} \times 36 = 20° \text{ C}$$

To convert centigrade to Fahrenheit, the reverse procedure is necessary. First multiply the reading on the centigrade thermometer by 9/5 and then add 32 to the result–

AT. 32

Figure 5-13.–Fahrenheit and centigrade thermometers.

$$\frac{9}{5}(20) + 32$$

$$36 + 32 = 68° \text{ F}$$

One way to remember when to use 9/5 and when to use 5/9 is to keep in mind that the Fahrenheit scale has more divisions than the centigrade scale. In going from centigrade to Fahrenheit, multiply by the ratio that is larger; in going from Fahrenheit to centigrade, use the smaller ratio.

Another method of temperature conversion which uses these same ratios is based on the fact that the Fahrenheit and centigrade scales both register the same temperature at -40°; that is, -40°F equals -40°C. This method of conversion, sometimes called the "40 rule," proceeds as follows:

1. Add 40 to the temperature which is to be converted. Do this whether the given temperature is Fahrenheit or centigrade.
2. Multiply by 9/5 when changing centigrade to Fahrenheit; by 5/9 when changing Fahrenheit to centigrade.
3. Subtract 40 from the result of step 2. This is the answer.

As an example to show how the 40 rule is used, convert 100° C to the equivalent Fahrenheit temperature:

$$100 + 40 = 140$$

$$140 \times 9/5 = 252$$

$$252 - 40 = 212$$

Therefore, 100° C = 212° F. Remember that the multiplying ratio for converting F to C is 5/9, rather than 9/5. Also remember to always ADD 40 first, then multiply, then SUBSTRACT 40, regardless of the direction of the conversion.

It is important that all technicians be able to read thermometers and to convert from one scale to the other. In some types of electronic equipment, thermometers are provided as a check on operating temperatures. Thermometers are also used to check the temperature of a charging battery.

SOLID THERMOMETERS.–Because the range of all liquid thermometers is extremely limited, other methods of thermometry are necessary. Most liquids freeze at temperatures

GESEL 13252

191

between 0° and -200° centigrade. At the upper end of the temperature range where high heat levels are encountered, the use of liquid thermometers is limited by the high vapor pressures of those liquids. Among the most widely used types of thermometers other than the standard liquid thermometers are the resistance thermometer, and the thermocouple.

The RESISTANCE THERMOMETER makes use of the fact that the resistance of metals changes as the temperature changes. (See chapter 6 of Basic Electricity, NavPers 10086-B.) This type thermometer is usually constructed of platinum wire wound on a mica form and enclosed in a thin-walled silver tube. It is extremely accurate from the lowest temperature to the melting point of the unit.

The THERMOCOUPLE shown in figure 5-14 is essentially an electric circuit. Its operation is based on the principle that when two unlike metals are joined and the junction is at a different temperature than the remainder of the circuit, an electromotive force is produced. This electromotive force can be measured with great accuracy by a galvanometer. Thermocouples can be located whereever measurement of the temperature is important and wires run to a galvanometer located at any convenient point. By means of a rotary selector switch, one galvanometer can read the temperatures at any of a number of widely separated points.

Thermal Expansion

Nearly all substances expand or increase in size when their temperature increases. Railroad tracks are laid with small gaps between the sections to prevent buckling when the temperature increases in summer. Concrete pavement has strips of soft material inserted at intervals to prevent buckling when the sun heats the roadway. A steel building or bridge is put together with red-hot rivets so that when the rivets cool they will shrink and the separate pieces will be pulled together very tightly.

As a substance is expanded by heat, the weight per unit volume decreases. This is because the weight of the substance remains the same while the volume is increased by the application of heat. Thus the density decreases with an increase in temperature.

Experiments show that for a given change in temperature, the change in length or volume is different for each substance. For example, a given change in temperature causes a piece of copper to expand nearly twice as much as a piece of glass of the same size and shape. For this reason, the lead wires into an electronic tube cannot be made of copper but must be made of a metal that expands at the same rate as glass. If the metal does not expand at the same rate as the glass, the vacuum in the tube is broken by air leaking past the wires in the glass stem. The metal usually used for this purpose is an alloy called "Covar."

The amount that a unit length of any substance expands for a 1° rise in temperature is known as the coefficient of linear expansion for that substance.

COEFFICIENTS OF EXPANSION.–To estimate the expansion of any object, such as a steel rail, it is necessary to know three things about it–its length, the rise in temperature to which it is subjected, and its rate or coefficient of expansion. The amount of expansion is expressed by the following equation:

expansion = coefficient x length

x rise in temperature

or

$$e = kl(t_2 - t_1)$$

In this equation, the letter k represents the coefficient of expansion for the particular substance. In some instances, the Greek letter α is used to indicate the coefficient of linear expansion.

AT.33

Figure 5-14.–Thermocouple.

13253

PROBLEM: If a steel rod measures exactly 9 feet at 21° C, what is its length at 55° C? (The coefficient of linear expansion for steel is 11×10^{-6}.) If the equation $e = kl\ (t_2 - t_1)$ is used, then

$$e = (11 \times 10^{-6}) \times 9 \times (55 - 21)$$

$$e = 0.000011 \times 9 \times 34$$

$$e = 0.003366$$

This amount, when added to the original length of the rod, makes the rod 9.003366 feet long. (Since the temperature has increased, the rod is longer by the amount of e. If the temperature had been lowered, the rod would have become shorter by a corresponding amount.)

The increase in the length of the rod is relatively small; but if the rod were placed where it could not expand freely, there would be a tremendous force exerted due to thermal expansion. Thus, thermal expansion must be taken into consideration when designing ships, buildings, and all forms of machinery.

Table 5-2 is a list of the coefficients of linear expansion of some substances.

Table 5-2.–Expansion coefficients.

Substance	Coefficient of linear expansion
Aluminum	24×10^{-6}
Brass	19×10^{-6}
Copper	17×10^{-6}
Glass	4 to 9×10^{-6}
Covar	4 to 9×10^{-6}
Steel	11×10^{-6}
Quartz	0.4×10^{-6}
Zinc	26×10^{-6}

A practical application for the differences in the coefficients of linear expansion is the thermostat. This instrument comprises two strips of dissimilar metal fastened together. When the temperature changes, a bending takes place due to the unequal expansion of the metals (fig. 5-15). Thermostats are used in overload relays for motors, in temperature sensitive switches, and in electric ovens. (See fig. 5-16.)

The coefficient of surface or area expansion is approximately twice the coefficient of linear expansion. The coefficient of volume expansion is approximately three times the coefficient of linear expansion. It is interesting to note that in a plate containing a hole, the area of the holes expands at the same rate as the surrounding material. In the case of a volume enclosed by a thin solid wall, the volume expands at the same rate as would a solid body of the material of which the walls are made.

CHANGE OF STATE

A thermometer placed in melting snow behaves in a strange manner. The temperature of the snow rises slowly until it reaches 0°C. Provided that the mixture is stirred constantly, it remains at that point until all the snow has changed to water; when all the snow has melted, the temperature again begins to rise. A definite amount of heat is required to change the snow to water at the same temperature. This heat is required to change the water from crystal form to liquid form.

Heat of Fusion

Eighty gram-calories of heat are required to change 1 gram of ice at 0°C to water at

AT.34

Figure 5-15.–Compound bar.

13254

AT. 35

Figure 5-16.–Thermostat.

0° C. In English units, the heat required to change 1 pound of ice at 32° F to water at 32° F is 144 Btu's. These values are called the HEAT OF FUSION of water. The heat used while the ice is melting represents the work done to produce the change of state. Since 80 calories are required to change a gram of ice to water at 0° C, when a gram of water is frozen it gives up 80 calories.

Many substances behave very much like water. At a given pressure, they have a definite heat of fusion and an exact melting point. There are many materials, however, which do not change from a liquid to a solid state at one temperature. Molasses, for example, gets thicker and thicker as the temperature decreases; but there is no exact temperature at which the change of state occurs. Wax, celluloid, clay, and glass are other substances which do not change from a liquid to a solid state at any particular temperature. In fact, measurements of the glass thickness at the bottom of windows in ancient cathedrals tend to indicate that the glass is still flowing at an extremely slow rate. Most types of solder used in electronics maintenance also tend to become mushy before melting.

Heat of Vaporization

Damp clothing dries rapidly under a hot flatiron but not under a cold one. A pool of water evaporates more rapidly in the sun than in the shade. Thus, it may be concluded that heat has something to do with evaporation. The process of changing a liquid to a vapor is similar to that which occurs when a solid melts.

If a given quantity of water is heated until it evaporates–that is, changes to a gas (vapor)–a much greater amount of heat is used than that which is necessary to raise the same amount of water to the boiling point. For example, several hundred calories are required to change 1 gram of water to vapor at a given temperature. It takes 972 Btu's to change 1 pound of water at 212° F to water vapor (steam) at 212° F. The amount of heat necessary for this change is called the HEAT OF VAPORIZATION of water. Over five times as much heat is required to change a given amount of water to vapor than to raise the same amount of water from the freezing to the boiling point.

BOILING.–When water is heated, some vapor forms before the boiling point is reached. The change from water to vapor occurs as follows: As the water molecules take up more and more energy from the heating source, their kinetic energy increases. The motion resulting from the high kinetic energy of the water molecules causes a pressure which is called the vapor pressure. As the velocity of the molecules increases, the vapor pressure increases. At sea level, atmospheric pressure is normally 29.92 inches of mercury. The boiling point of a liquid is that temperature at which the vapor pressure equals the external or atmospheric pressure. At normal atmospheric pressure at sea level, the boiling point of water is 100° C or 212° F.

While the water is below the boiling point, a number of molecules acquire enough kinetic energy to break away from the liquid state into a vapor. For this reason some evaporation slowly takes place below the boiling point. At the boiling point or above, large numbers of molecules have enough energy to change from liquid to vapor and the evaporation takes place much more rapidly.

If the molecules of water are changing to water vapor in an open space, the air currents carry them away quickly. In a closed container,

13255

they rapidly become crowded and some of them bounce back into the liquid as a result of collisions. When as many molecules are returning to the liquid state as are leaving it, the vapor is said to be saturated. Experiments have shown that saturated vapor in a closed container exerts a pressure and has a given density at every temperature.

LIGHT

The exact nature of light is not fully understood, although men have been studying the subject for many centuries. Some experiments seems to show that light is composed of tiny particles, and some indicate that it is made up of waves.

First one theory and then the other attracted the approval and acceptance of the physicists. Today there are scientific phenomena which can be explained only by the wave theory and another large group of occurrences which can be made clear by the particle or corpuscular theory. Physicists, constantly searching for some new discovery which would bring these contradictory theories into agreement, gradually have come to accept a theory concerning light which is a combination of these two views.

According to the view now generally accepted, light is a form of electromagnetic radiation; that is, light and similar forms of radiation are made up of moving electric and magnetic forces.

CHARACTERISTICS

When light waves, which travel in straight lines, encounter any substance, they are transmitted, reflected, or absorbed. (See fig. 5-17.) Those substances which permit clear vision through them, and which transmit almost all the light falling upon them, are said to be transparent. Those substances which allow the passage of part of the light, but appear clouded and impair vision substantially, are called translucent. Those substances which transmit no light are called opaque.

Objects which are not light sources are visible only because they reflect all or part of the light reaching them from some luminous source. If light is neither transmitted nor reflected, it is absorbed or taken up by the medium.

AT.36

Figure 5-17.—Light rays reflected, absorbed, and transmitted.

When light strikes a substance, some absorption and reflection always take place. No substance completely transmits, reflects, or absorbs all the light which reaches its surface. Figure 5-17 shows how glass transmits, absorbs, and reflects light.

Reflection

Light waves obey the law of reflection in the same manner as other types of waves. Optical devices incorporated specifically for the purpose of reflecting light are generally classed as mirrors. They may be of a polished opaque surface, or they may be a specially coated glass. In the case of the glass mirror, there is some refraction as well as reflection; however, if the glass is of good quality and not excessively thick, the refraction will cause no trouble. The following discussion is based on the polished surface type mirror.

Several classes of mirrors are illustrated in figure 5-18. All the devices work on the basis of the previously discussed law of reflection, and the applications are only briefly summarized here. Basically, the reflector is used to change the direction of a light beam (A), to focus a beam of light (B), or to intensify the illumination of an area (C).

In figure 5-18 (A), the angle of the reflected light may be changed to a greater or lesser degree by merely changing the angle at which the incident light impinges upon the mirror. In figure 5-18 (B), the focusing action of a concave mirror is indicated. The point of focus may be made any convenient distance from the reflector by proper selection of the arc of curvature of the mirror–the sharper the curvature, the shorter

the focal length. In figure 5-18 (C), the principal of intensification of illumination for a specific area is illustrated. The flashlight is an example of this application. In the system shown, note that the light source (bulb) is located approximately at the principal focus point, and that all rays reflected from the surface are parallel. Also note that the reflector alone does not concentrate all the rays—some are transmitted without being reflected and are not included in the principal beam.

Refraction

As light passes through a transparent substance, it travels in a straight line. However, as it passes into or out of that substance, it is refracted in the same manner as other waves which were discussed earlier. Refraction of light waves results from the fact that light travels at slightly different velocity in different transparent mediums. In order to simplify the problem of understanding the action of light reflection and to make it possible to predict the outcome of specific applications, many transparent substances have been tested for refractive effectiveness. The ratio of the speed of light in air to its speed in each transparent substance is called the "index of refraction" for that substance. For example, light travels about one and one-half times as fast in air as it does in glass, so the index of refraction of glass is about 1.5. When using the law of refraction in connection with light, a "denser" medium refers to a medium with a higher index of refraction.

Refraction through a piece of plate glass is shown in figure 5-19. The ray of light strikes the glass plate at an oblique angle. If it were to continue in a straight line, it would emerge from the plate at point A; but in accordance with the law of refraction, it is bent toward the normal and emerges from the glass at point B. Upon entering the air, the ray does not continue on its path but is bent away from the normal and along the path BC in the air. If the two surfaces of the glass are parallel, the ray leaving the glass is parallel to the ray entering the glass. The displacement depends upon the thickness of the glass plate, the angle of entry into it, and the index of refraction for the glass.

All rays striking the glass at any angle other than perpendicular are refracted in the same manner. In the case of a perpendicular ray, no

13257

AT.38

Figure 5-19.–Refraction through a piece of plate glass.

refraction takes place, and the ray continues through the glass and into the air in a straight line.

PRISMS.–When a ray of light passes through a flat sheet of glass, it emerges parallel to the incident ray. This holds true only when the two surfaces of the glass are parallel. When the two surfaces are not parallel, as in a prism, the ray is refracted differently at each surface of the glass and does not emerge parallel to the incident ray.

Figure 5-20 (A) shows that both refractions are in the same direction, and that the ray coming out of the prism is not parallel to the ray going into it. The law of refraction explains what has happened. When the ray entered the prism, it was bent toward the normal; and when it emerged, it was bent away from the normal. Notice that the deviation is the result of the two normals not being parallel.

If two triangular prisms are placed base to base, as in figure 5-20 (B), parallel incident rays passing through them are refracted and caused to intersect. The rays passing through different parts of the prisms, however, do not intersect at the same point. In the case of two prisms there are only four refracting surfaces. The light rays from different points on the same plane are not refracted to a point on the same plane behind the prism. They emerge from the prisms and intersect at different points along an extended common baseline as illustrated by points A, B, and C of figure 5-20 (B).

Parallel incident light rays falling upon two prisms that have been joined apex to apex (fig. 5-20 (C), are spread apart. The upper prism

AT.39

Figure 5-20.–Passage of light through a prism. (A) Single prism; (B) two prisms, base to base; (C) two prisms, apex to apex.

13258

refracts light rays toward its base; the lower prism refracts light rays downward toward its base, causing the two sets of rays to diverge.

POSITIVE LENSES.–A positive (convergent) lens acts like two prisms base to base with their surfaces rounded off into a curve. Rays that strike the upper half of the lens bend downward, and rays that strike the lower half bend upward. A good lens causes all wavelengths within each ray to cross at the same point behind the lens as shown in figure 5-21 (A).

When the incident ray of light enters the denser medium (the lens), it bends toward the normal. When it passes through into the less dense medium (the air), it bends away from the normal. Figure 5-21 (B) illustrates the refraction of only one ray of light, but all rays passing through a positive lens are affected in the same way. All incident light rays either parallel or slightly diverging will converge to a point after passing through a positive lens.

AT.40

Figure 5-21.–Positive lenses.

The only ray of light that can pass through a lens without bending is the ray which strikes the first surface of the lens at a right angle, perpendicular or normal to the surface. It passes through that surface without bending and strikes the second surface at the same angle. It leaves the lens without bending. This ray is shown in figure 5-21 (B).

Positive lens and convergent lens are synonymous terms, since either of them may be used to describe the action of a lens which focuses (brings to a point of convergence) all light rays passing through it. All simple positive lenses are easy to identify since they are thicker in the center than at the edges. The three most common types of simple positive lenses are shown in figure 5-21 (C).

NEGATIVE LENSES.–Figure 5-22 illustrates the refraction of light rays by two prisms apex to apex. If the prism surfaces are rounded the result is a negative (divergent) lens. A negative lens is called a divergent lens since it does not focus the rays of light passing through it. Light rays passing through a negative lens diverge or spread apart as shown in figure 5-22 (A).

Figure 5-22 (B) applies the law of refraction to one ray of light passing through a negative lens. Just as in a positive lens, a ray of light passing through the center of a negative lens is not affected by refraction and passes through without bending.

Three simple negative lenses are shown in figure 5-22 (C). They are often referred to as concave lenses and are readily identified by their concave surfaces. The simple negative lenses are thicker at the edges than at the center. They are generally used in conjunction with simple positive lenses where their primary use is to assist in the formation of a sharper image by helping to eliminate or subdue various defects present in an uncorrected simple positive lens.

FREQUENCIES AND COLOR

The electromagnetic waves which produce the sensation of light are all very high in frequency, which means that they have very short

AT.41

Figure 5-22.–Negative lenses.

wavelengths. These wavelengths are measured in millimicrons (millionths of millimeters, or 10^{-9} meters). Figure 5-23 indicates that light with a wavelength of 700 millimicrons is red, and that a light with a wavelength of 500 millimicrons is blue-green. This drawing is subject to erroneous interpretation. In actual fact, the color of light is dependent on its frequency, not its wavelength.

When the wavelength of 700 millimicrons is measured in air, it produces a color known as red, but the same wave measured in another medium has a wavelength other than 700 millimicrons. When red light which has been traveling is air enters glass, is loses speed and its wavelength becomes shorter or compressed, but it continues to be red. This illustrates that the color of light is dependent upon frequency and not on wavelength. The color scale in figure 5-23 is based on the wavelengths in air.

All color-component wavelengths of the visible spectrum are present in equal amounts in white light. Variations in composition of the component wavelengths result in other characteristic colors.

When a beam of white light is passed through a prism, as shown in figure 5-23, it is refracted and dispersed into its component wavelengths. Each of these wavelengths reacts differently on the eye which then sees the various colors that compose the visible spectrum. The visible spectrum is recorded as a mixture of red, orange, yellow, green, blue, indigo, and violet. It can be readily demonstrated that white light results when the PRIMARIES (red, green, and blue) are mixed together in over-lapping beams of light. (NOTE: These are not the primaries used in mixing pigments.) Furthermore, the COMPLEMENTARY or secondary colors (magenta, yellow, and cyan) may be shown with equal ease by mixing any two of the primary colors in overlapping beams of light. Thus, red and green light mixed in equal intensities will make yellow light; green and blue will produce blue-green light which is termed cyan; and blue and red light correctly mixed will render magenta (a purplish red).

It should be noted that a few modern texts vary the treatment of the color scale slightly from the seven spectral colors. This is due partly to developments in the mixing values of pigments (paints). This difference in approach is based on a theory that the retina of the eye is equipped with three varying groups of nerves, sensitive roughly to red, green, and blue-violet light.

SOUND

BASIC CONSIDERATIONS

The term sound as generally used refers to hearing; but when used in physics, the term has to do with a particular type of wave motion and with the generation, propagation, transmission, characteristics, and effects of those waves.

13269

REFRACTION OF LIGHT BY A PRISM. THE LONGEST RAYS ARE INFRARED; THE SHORTEST, ULTRAVIOLET

AT.42

Figure 5-23.–Electromagnetic wavelengths and the refraction of light.

One example of the generation and propagation of sound waves is the tuning fork discussed earlier in this chapter. Any object which moves rapidly to and fro, or which vibrates rapidly in such a manner as to disturb the surrounding medium, may become a sound source. Sound requires three components–a source, a medium for transmission, and a detector. As widely different as sound sources may be, the waves they produce have certain basic characteristics.

Wave Motion

Sound waves are longitudinal type waves which rely on a physical medium for propagation and transmission. Since the waves are transmitted by the compression and rarefaction of particles of matter in the medium, they cannot be transmitted through a vacuum. Sound waves are similar to waves of other types in that they can be reflected, absorbed, or refracted according to the laws previously discussed; they are also subject to the Doppler effect.

The major differences between the waves of sound and the waves of heat and light are the frequencies, the nature of the wave, and the velocities of wave travel.

Frequencies

Sound waves vary in length; a long wavelength is heard as a low sound, while a short wavelength is heard as a high sound. If the sound is below 15 hertz per second or above 20,000 hertz per second, it normally cannot be heard by the human ear. The frequency range over which sound can be heard is called the audible range, and the sounds heard are known as sonics. Sounds below 15 hertz per second are subsonics; those above 20,000 hertz per second are ultrasonics.

Conduction Media and Velocity of Transmission

In any uniform medium under given physical conditions, sound travels at a definite speed. In some substances, the velocity of sound is higher than in others. Even in the same medium under different conditions of temperature and pres-

13261

PREFACE

Machine drafting, Volume I, is based on practical experience acquired while teaching the subject for many years. It is organized into a series of drawing plates that teach the elements of drafting and drafting skills along with the making of typical shop drawings. Brief information has been given relative to instruments and equipment, lines, lettering, and constructions. More will be learned by the student as he needs it, in actually carrying out drafting problems and in added information conveyed in Volumes II and III.

Many drawing problems in the book may be done either free-hand or with drawing instruments; the possibility of such choice is indicated. Others, involving geometrical constructions, must be done with drawing instruments.

It is the author's fervent wish that the student draftsman concentrate first on quality and then on speed and eventually combine both factors to become a happy and proficient draftsman.

sure, the velocity of sound varies. Density and elasticity of a medium are basic physical properties which govern the velocity of sound.

At a given temperature and pressure, all sound waves travel at the same speed in air, regardless of frequency or wavelength. The speed of sound, however, does increase with temperature at the rate of 2.0 feet per second (fps) per degree centigrade. For practical purposes, the speed of sound in air may be considered 1,100 fps. Refer to table 5-3 for speed of sound in various media at different temperatures.

As previously stated, a sound wave is a compressional wave transmitted through an elastic medium. Sound travels faster through water (4,800 fps) than air (1,087 fps) because the elasticity of water is greater than that of air.

For a fixed temperature, the velocity of sound is constant for any medium and is independent of the period, frequency, or amplitude of the disturbance. Thus, the velocity of sound in air at 0° C (32° F) is 1,087 fps and increases by 2 fps for each degree centigrade rise in temperature (1.1 fps for each degree Fahrenheit).

The velocity of sound also varies with a change in altitude. With an increase in altitude, the atmospheric pressure is reduced, and the medium is less dense. Sound waves travel slower in a less dense medium. Therefore, it may be considered that the velocity of sound varies inversely with the altitude.

Table 5-3.—Comparison of velocity of sound in various media.

Medium	Temperature (° F)	Velocity (ft/sec)
Air	32	1,087
Air	68	1,127
Fresh water	32	4,629
Fresh water	68	4,805
Salt water	32	4,800
Salt water	68	4,953
Steel	32	16,410
Steel	68	16,850

Characteristics

Numerous terms are used to convey impressions of sounds, including whistle, scream, rumble, and hum. Most of these are classified as noises in constrast to musical tones. The distinction is based on the regularity of the vibrations, the degree of damping, and the ability of the ear to recognize components having a musical sequence.

The ear can distinguish tones that are different in pitch, intensity, or quality. Each of these characteristics is associated with one of the properties of the vibrating source or of the waves that the source produces. Thus, pitch is determined by the number of vibrations per second, intensity by the amplitude of the wave motion, and quality by the number of overtones (harmonics) which the wave contains. A sound wave can best be described by its frequency rather than by its velocity or wave-length, as both the velocity and the wavelength change when the temperature of the air changes.

PITCH.–The term pitch is used to describe the frequency of a sound. The outstanding recognizable difference between the tones produced by two different keys on a piano is a difference in pitch. The pitch of a tone is proportional to the number of compressions and rarefactions received per second, which in turn is determined by the vibration frequency of the sounding source.

Pitch is usually measured by comparison with a standard. The standard tone may be produced by a tuning fork of known frequency or by a siren whose frequency is computed for a particular speed of rotation. By regulating the speed, the pitch of the siren is made equal to that of the tone being measured. The ear can determine this equality directly if the two sources are sounded alternately, or by the elimination of beats by regulating the speed of the siren if the two sources are sounded together.

INTENSITY.–When a bell rings, the sound waves spread out in all directions and the sound is heard in all directions. When a bell is struck lightly, the vibrations are of small amplitude and the sound is weak. A stronger blow produces vibrations of greater amplitude in the bell, and the

13262

sound is louder. It is evident that the amplitude of the air vibrations is greater when the amplitude of the vibrations of the source is increased. Hence the loudness of the sound depends on the amplitude of the vibrations of the sound waves. As the distance from the source increases, the energy in each wave spreads out, and the sound becomes weaker.

The intensity of sound is the energy per unit area per second. In a sound wave of simple harmonic motion, the energy is half kinetic and half potential; half is due to the speed of the particles, and half is due to the compression and rarefaction of the medium. These two energies are 90° out of phase at any instant–that is, when the speed of particle motion is at a maximum, the pressure is normal; and when the pressure is at a maximum or a minimum, the speed of the particles is zero.

The loudness of sound depends upon both intensity and frequency. The intensity of a sound wave in a given medium is proportional to the following 4 quantities:

1. Square of the frequency of vibration.
2. Square of the amplitude.
3. Density of the medium.
4. Velocity of propagation.

At any distance from a point source of sound, the intensity of the wave varies inversely as the square of the distance from the source.

As a sound wave advances, variations in pressure occur at all points in the transmitting medium. The greater the pressure variations, the more intense the sound wave will be. It can be shown that the intensity is proportional to the square of the pressure variation regardless of the frequency. Thus, by measuring pressure changes, the intensities of sounds having different frequencies can be compared directly.

QUALITY.–Most sounds and musical notes are not pure tones. They are mixtures of tones of different frequencies. The tones produced by most sources can be represented by composite waves in which the sound of lowest pitch, the fundamental tone, is accompanied by several harmonics or overtones having frequencies that are 2, 3, 4 or more times that of the fundamental frequency. The quality of a tone depends on the number of overtones present and on their frequencies and intensities relative to the fundamental tone. It is this characteristic of difference in quality that distinguishes tones of like pitch and intensity when sounded on different types of musical instruments (piano, organ, violin, etc.).

ACOUSTICS

Acoustics is the science of sound, including its propagation, transmission, and effect. The performance of an announcing system or sound system when used in a room or enclosed space depends on the acoustical characteristics of the enclosure. Sound originating in an enclosed space is partly reflected and partly absorbed by enclosing surfaces such as the walls, ceiling, and floor of a room. This action introduces echoes and reverberations, which may seriously impair the quality or character of the sound.

Acoustical Disturbances

Light is often thought of first whenever reflection is discussed; however, reflection is equally common in other waves. As an example, echoes are caused by reflection of sound waves.

ECHO.–An ECHO is the repetition of a sound caused by the reflections of sound waves. When a surface of a room is situated so that a reflection from it is outstanding, it appears as a distinct echo, and is heard an appreciable interval later than the direct sound. If the surface is concave, it may have a focusing effect and concentrate the reflected sound energy at one locality. Such a reflection may be several levels higher in intensity than the direct sound, and its arrival at a later time may be particularly disturbing. Some possible remedies for this condition are as follows:

1. Cover the offending surface with absorbing material to reduce the intensity of the reflected sound.
2. Change the contour of the offending surface and thus send the reflected sound in another direction.
3. Locate the loudspeaker in a different position.
4. Vary the amplitude or the pitch of the signal.

REVERBERATION is the persistence of sound due to the multiple reflection of sound waves between several surfaces of an enclosure. It is one of the most common acous-

13263

tical defects of a large enclosure. Its duration varies directly with the time interval between reflections (the size of the enclosure) and inversely with the absorbing efficiency of the reflecting surfaces. The result is an overlapping of the original sound and its images. If excessive, reverberation causes a general confusion that is detrimental to speech intelligibility. The hangar deck of an aircraft carrier is an example of an extremely reverberant area. The volume is large, and the hard steel interior surfaces offer very little absorption to sound.

If a single loudspeaker is mounted in a large reverberant area, such as a hangar deck, the intelligibility directly in front of the loudspeaker is satisfactory. The intelligibility decreases rapidly with an increase of either the distance from the loudspeaker or the angle between the listener and the loudspeaker's sound axis. In other words, sound from a loudspeaker in a reverberant space is composed of direct sound that reaches the listener directly without any reflection, and indirect sound that has received at least one reflection.

Intelligibility under these conditions is related to the ratio of direct sound to indirect sound. As the listener moves away from the loudspeaker, the ratio of direct sound to indirect sound at the listening position decreases, and the intelligibility decreases correspondingly. Hence, in a highly reverberant space the intelligibility decreases with distance from the loudspeaker.

To prevent the sound from becoming unintelligible in a highly reverberant space, several speakers can be installed about the area rather than just one. The power requirements remain the same; one 25-watt speaker could be replaced by 5 speakers, each consuming 5 watts. This would greatly increase the direct-to-indirect sound ratio.

INTERFERENCE.–Two sound waves moving through the same medium at the same time will advance independently, each producing the same disturbance as if it were alone. The resultant of the two waves can be obtained by adding algebraically the ordinates (instantaneous magnitudes) of the component waves.

Two sound waves of the same frequency, in phase with each other and moving in the same direction are additive. The resultant wave is in phase with, and has an amplitude equal to, the sum of the component waves.

Two sound waves of the same frequency, in phase opposition and moving in the same direction, are subtractive. If the component waves have equal amplitudes, the resultant wave is zero. This addition or subtraction of waves is often called interference.

Two sound waves of slightly different frequency and moving in the same direction produce a beat note. If the two waves originate from two vibrating sources at the same point, and the frequency of one wave is one vibration per second greater than that of the other at a particular instant, the sources will produce additive disturbances at some points and subtractive disturbances at some other points on the relative positions of the waves. These changes will continue to occur as long as the sources are kept vibrating.

The resultant wave has a periodic variation in intensity at a frequency equal to the difference between the original frequencies of the component waves. The difference frequency, referred to as the beat frequency, produces a type of pulsating interference particularly noticeable in sound waves. The effect of beat frequency, called beats, produces alternately loud and soft pulses or throbs. The effect is most pronounced when the component waves have equal amplitudes.

STANDING WAVES.–Two sound waves of equal frequency and amplitude moving in opposite directions through the same medium may produce standing waves. Standing waves are set up by the reaction of the two waves on each other. At certain points they are in phase and at other points they are 180° out of phase. Because their amplitudes are equal, when the two waves act in opposition on a particle, the particle remains motionless. At these points in a standing wave, there is no vibration and the points are called nodes. At the points where the two waves reinforce each other they produce maximum vibrations on a particle. These points are called antinodes. The distance between successive nodes (or antinodes) is a half wavelength.

RESONANCE.–Resonance, or sympathetic vibration, is a common problem encountered in acoustics. It is somewhat more serious than some of the other problems discussed, because

13264

the possibility exists for damage to equipment. Reverberation and resonance are frequently confused, but they are distinctly different in nature. Reverberation is a result of the reflection of sound waves and of the interaction between the direct and reflected sound. There is only a single source involved. In resonance, however, the offending object becomes a sound source under certain conditions. This may be explained by the following example:

Assume that the natural frequency of vibration of a steel shaft, which is weighted on one end and held firmly on the other, is 25 vibrations per second. Suppose that with the system at rest, a sound wave produces a force which acts on the shaft with a to-and-fro motion 125 times per second. This force sets the system vibrating at 125 vibrations per second. These vibrations would be of a small amplitude because the rod and weight are trying to vibrate at their natural rate of only 25 vibrations per second. During part of the time the system is resisting the driving force. The motion of the system in this case is called a forced vibration.

If the force is slowed from 125 vibrations per second to its natural frequency of 25 vibrations per second, the amplitude of vibration becomes very large. The amplitude will build up to a point where the driving force is enough to overcome the inertia of the system.

When these conditions exist, the system is said to be in resonance with the driving force, and sound waves are produced by this vibration.

A common example of resonance is found in a crystal oscillator circuit. When an alternating voltage is applied to a crystal that has the same mechanical (resonant) frequency as the applied voltage, it vibrates and only a small applied voltage is needed to sustain vibration. In turn, the crystal generates a relatively large voltage at its resonant frequency.

Measurement of Sound

The range of sound that the human ear can detect varies with the individual. The normal range extends from about 20 to 20,000 vibrations per second. In the faintest audible speech sounds, the intensity at the ear is about 10^{-16} watts/cm^2. At the threshold of feeling, the maximum intensity that the ear records as sound is about 10^{-4} watts/cm^2.

The human ear is a nonlinear unit that functions on a logarithmic basis.

If the ear is tested with tones of any one frequency, the threshold of audibility is reached when the intensity is reduced to a sufficiently low level so that the auditory sensation ceases. On the other hand, the threshold of feeling is reached when the intensity is increased to a sufficiently high level so that the sound produces the sensation of feeling and becomes painful. If this procedure is performed over a wide frequency range, the data can be used to plot two curves, one for the lower limit of audibility and the other for the maximum auditory response (fig. 5-24). Below the lower curve, the sound is too faint to be audible. Above the upper curve, the sensation is one of feeling rather than of hearing; that is, the sensation of sound is masked by that of pain. The area between the two curves shows the pressure ranges for auditory response at various frequencies. Note that the scales of frequency and pressure are logarithmic. An advance of one horizontal space doubles the frequency, and an advance of one vertical space multiples the pressure by ten.

SOUND UNITS.–The loudness of sound is not measured by the same type of scale used to measure length. Units of sound measurement are used that vary logarithmically with the amplitude of the sound variations. These units are the bel and decibel, which refer to the difference between sounds of unequal intensity or sound levels. The decibel, which is one-tenth of a bel, is the minimum change of sound level

AT.43

Figure 5-24.–Field of audibility.

13265

perceptible to the human ear. Hence, the decibel merely describes the ratio of two sound levels. A sound for which the power is 10 times as great as that of another sound level differs in power level by 1 bel, or 10 decibels. For example, 5 decibels may represent almost any volume of sound, depending on the intensity of the reference level or the sound level on which the ratio is based.

In sound system engineering, decibels are used to express the ratio between electrical powers or between acoustical powers. If the amounts of power to be compared are P1 and P2, the ratio in decibels (db) is

$$db = 10 \times \log \frac{(P2)}{(P1)}$$

(NOTE: When the logarithmic base is not indicated, it is assumed to be 10. The subjects of logarithms and logarithmic relationships are covered in Rate Training Manual, Mathematics, Vol. 2, NavPers 10071-B.)

If P2 is greater than P1, the decibel value is positive and represents a gain in power. If P2 is less than P1, the decibel value is negative and represents loss in power.

INTENSITY LEVEL.–An arbitrary zero reference level is used to accurately describe the loudness of various sounds. This zero reference level is the sound produced by 10^{-16} watts per square centimeter of surface area facing the source. This level approximates the least sound perceptible to the ear and is usually called the threshold of audibility. Thus, the sensation experienced by the ear when subjected to a noise of 40 decibels above the reference level would be 10,000 times as great as when subjected to a sound that is barely perceptible.

ACOUSTICAL PRESSURE.–Typical values of sound levels in decibels and the corresponding intensity levels are summarized in table 5-4. The values in this table are based on an arbitrary zero reference level. Note that for each tenfold increase in power, the intensity of the sound increases 10 decibels. The power intensity doubles for each 3-decibel rise in sound intensity.

POWER RATIO.–The decibel is used to express an electrical power ratio, such as the gain of an amplifier, the output of a microphone, or the power in a circuit compared to an arbitrary reference power level. The value of decibels is often computed from the voltage ratio SQUARED or the current ratio SQUARED. These are proportional to the power ratio for equal values of resistance. If the resistances are not equal, a correction must be made.

Table 5-4.–Values of sound levels.

Sound level (decibels)	Intensity level (watts/cm^2)
0	10^{-16}
60	10^{-10}
80	10^{-8}
100	10^{-6}
110	10^{-5}
120	10^{-4}
130	10^{-3}

To find the number of decibels from the voltage ratio, assuming that the resistances are equal, substitute E^2 for P in the basic equation:

$$db = 10 \times \log \frac{E2^2}{E1^2} = 10 \times \log \left(\frac{E2}{E1}\right)^2$$

$$db = 20 \times \log \frac{E2}{E1}$$

To find the number of decibels from the current ratio, assuming that the resistances are equal, substitude I^2 for P in the basic equation:

$$db = 10 \times \log \left(\frac{I2}{I1}\right)^2$$

$$db = 20 \times \log \frac{I2}{I1}$$

The power level of an electrical signal is often expressed in decibels above or below an arbitrary power level of 0.001 watt (1 milliwatt) as

132561

$$\text{dbm} = 10 \times \log \left(\frac{P}{0.001}\right)$$

where dbm is the power level above one milliwatt in decibels, and P is the power in watts.

The volume level of an electrical signal comprising speech, music, or other complex tones is measured by a specially calibrated voltmeter called a volume indicator. The volume levels read with this indicator are expressed in "v units" (vu), the number being numerically equal to the number of decibels above or below the reference volume level. Zero vu represents a power of 1 milliwatt dissipated in an arbitrary load resistance of 600 ohms (corresponds to a voltage of 0.7746 volt). Thus, when the vu meter is connected to a 600-ohm load, vu readings in decibels can be used as a direct measure of power above or below 1 milliwatt. For any other value of resistance the following correction must be added to the vu reading to obtain the correct vu value:

$$\text{vu} = \text{vu reading} + 10 \times \log \frac{600}{R}$$

where vu is the actual volume level, and R is the actual load, or resistance, across which the vu measurement is made. If the volume levels are indicated in units other than vu, the meter calibration, or reference level, must be stated with the decibel value.

132671

CHAPTER 6

ELECTRONIC POWER AND COOLING SYSTEMS

In order to operate and maintain the complex electronic installations of modern naval aircraft, the technician must be familiar with the electric power system of the particular aircraft with which he is associated. Since the electronic installations of aircraft vary widely according to the size and application of the aircraft, the electric power requirements and the electric system components of aircraft also vary. Therefore, the technician must also have a basic understanding of the component parts of the electric system–the power generation equipment, the conversion units, the power control, regulation, and protection components, and the general distribution systems–of typical aircraft.

Today's technician must also have an understanding of the capabilities and limitations of the auxiliary power sources provided for use in ground servicing and maintenance of aircraft. He must be able to operate these units, and must be familiar with the proper procedures for connecting and disconnecting the auxiliary power units to the aircraft. He must know the proper procedures for servicing the auxiliary units, and must observe and enforce all safety precautions and regulations concerning these operations.

The technician must also know the requirements for cooling the various electronic equipment while on the ground. He must be familiar with the sources of auxiliary air and cooling. He must know the operating procedures, as well as the capabilities and limitations of the various cooling units.

This chapter is devoted to a discussion of these topics. In most sections, the topics are discussed in general; in a few instances details are presented as they pertain to specific topics or items of equipment. Coverage of equipments is limited to those expected to be in common usage during the life of this manual.

TYPICAL AIRCRAFT SYSTEMS

The electric power system of an aircraft consists of the power source and its associated controls, the generation system and its associated control and regulation systems, the conversion units, the feeder and distribution system and its component parts, and the various protective devices used throughout the installation.

Most older types of aircraft used engine-driven generators to produce d-c power at a nominal 27.7 volts. Inverters and dynamotors were used as conversion units to produce the voltages required for operation of the individual equipment. With the comparatively simple installations then in use, this arrangement was satisfactory; however, as the installations became more complex, weight problems arose. The increased weight (which resulted from the addition of more and more inverters and dynamotors) soon became prohibitive. A new approach to the problem was required.

As part of the overall effort to standardize aircraft and electronic installations, the supply and distribution of power offered a logical starting point. The first step was to standardize the supply voltages and power frequencies, and to use generators which would provide the required power. Later in the standardization program, the generation of d-c power was discontinued, and the primary power became exclusively a.c.; the d-c requirement was supplied through transformer-rectifiers. This re-

Page 13268

duced the number of voltages generated, reduced the number of rotary devices, and allowed the use of smaller conductors in the distribution system. The result was a drastic decrease in the total weight of a given installation, which in turn permitted a more complex installation for a given weight allowance.

Even a partial listing of the considerations involved in any discussion of aircraft electric systems must include the following items in order to be of any real value:

1. A "main generating source" refers to all generator units driven by a specified engine; thus a single-engine aircraft can have only one main source.

2. Multiengine aircraft may have a main generating subsystem for each engine. This is the usual practice, but it is not universally followed.

3. In multigenerator systems, provisions may or may not be made for parallel operation of generators producing similar power. If parallel operation is provided, provisions must also be made for individual operation of the subsystems in the event of a failure within the paralleling system.

4. Adequate frequency regulation and stability in a-c generation systems required some method of speed control of the generator's rotor drive mechanism.

5. Provisions must be made to insure that adequate power is available in each mode of operation. In the event of failure of the aircraft engine or its associated generation system, the maximum amount of power which can be produced is decreased. In the case of single-engine aircraft this automatically constitutes an emergency situation.

6. The failure of a single generator or engine in a multiple installation does not constitute the same degree of emergency as the same failure in a single-engine installation. Although some restrictions are placed on operational capabilities, some degree of safety may usually be maintained with the remaining engines and generators.

7. Provisions should be made to enable use of external power sources for starting the engines while on the ground and for ground operation without using the aircraft engines. The aircraft electric system must include provisions to prevent applying both internally-generated power and externally-furnished power to the system at the same time.

AIRCRAFT ELECTRIC SYSTEMS

The electric system of each model aircraft has features which are peculiar to it alone, while other features are common to most models. This section is devoted primarily to a general discussion of the electrical system of a typical aircraft, with some subsequent details concerning the electric systems of actual aircraft.

Source of Power

The basic source of power for the electrical system is the aircraft engine. An a-c generator requires a constant rotational speed in order to produce a constant frequency output. In most modern aircraft, a constant speed drive (CSD) unit is inserted between the aircraft engine and the a-c generator for this purpose.

The constant speed drive unit acts as a variable-ratio differential transmission system which converts the variable speed of the engine to the constant speed required by the generator. The engine is mechanically coupled to the input of the CSD unit; the output of the CSD is mechanically coupled to the rotor of the generator. Internal coupling between the input and output sections of the CSD unit is usually hydraulic, using the engine's oil supply as the transmission coupling medium. Output speed of rotation is controlled by means of mechanical governors and/or electronic speed regulators.

Generation System

The heart of the electric generation system is the constant-speed, wye-connected, a-c generator. This unit normally produces a 3-phase output voltage of about 120/208 volts at 400 Hz which is subsequently regulated to 115/200 volts. The basic theory of a-c generators is discussed in chapter 16 of Basic Electricity, NavPers 10086-B.

An underspeed switch is normally connected to the output shaft of the CSD unit. This is a centrifugally-operated switch and is normally in the open position; it closes only when the output end of the CSD (which is also the gen-

10269

erator shaft) reaches a preset speed of rotation. When the switch is open, the electrical system cannot be energized. An overspeed switch is also sometimes used.

STATIC EXCITER.–In most aircraft generators, the rotor receives its excitation from a separate static exciter rather than from a primary rotating exciter (as in the system described in Basic Electricity, NavPers 10086-B). Use of the static exciter eliminates the commutator and its associated problems; coupling from the exciter output to the generator rotor is accomplished through the simpler brush and slipring arrangement.

The heart of the static exciter is the saturable current potential transformer (SCPT). Figure 6-1 shows one phase of the exciter operation. The SCPT is a 3-phase transformer with four separate windings. The current windings carry all of the output current of the generator and, when the load equipment is being used, these windings supply most of the field power requirements. The potential winding is used mainly during initial buildup (when there is no load current flowing).

In series with the potential winding is a linear reactor which shifts the phase of the signal derived from line voltage and reduces it to the correct magnitude. The third winding is the transformer output winding which delivers field power to the generator. The output winding voltage is rectified in a 3-phase full-wave rectifier circuit and fed to the field of the generator (through a brush and slipring assembly).

The last winding is the d-c control winding, which is connected to the output of the voltage regulator and controls the saturation of the transformer core. As more control current flows in the control winding, there is less coupling between the primaries and the secondary or output transformer windings. The control winding (in effect) changes the unit from an iron core to an air core transformer by controlling the saturation level of the magnetic cores.

PARALLEL OPERATION. – Most multiengine aircraft utilize more than one a-c generator to supply the electrical and electronic loads. The practice of operating multigenerator systems in parallel makes possible the equal distribution of loads between the generators. Parallel operation simplifies the problem of transferring loads when one of the generators is removed from the line and permits a finer frequency control than is provided by the basic constant speed drive governor.

Paralleling circuitry senses both the frequency and the phase relationship between individual generators. If either the frequency

AT.44

Figure 6-1.–Static exciter, simplified diagram.

13270

or the phase relationship of the generators is not within permissible limits, parallel operation is not possible. When both these parameters are within tolerance, a paralleling relay operates and supplies power to the coil of a bus tie contactor. Once the bus tie contactor energizes, it is kept closed through an auxiliary set of its own contacts. If the operation of either generator exceeds allowable limits, the bus tie contactor opens and the generators are returned to individual operation.

Division of generator loads involves distributing both the real load (watts) and the reactive load (volt-amperes, reactive). In most parallel systems real loads are equalized by controlling the torque input of each CSD as a function of the difference in watts output. In systems which also equalize the reactive loads, an imbalance activates a reactive biasing circuit. This circuit develops error/correction signals for each generator so as to reestablish a reactive output current balance between the individual generators.

SINGLE-PHASE PMG.–Some main 3-phase a-c generators incorporate a small single-phase permanent magnet generator (PMG) as an integral part of the unit. The permanent magnet rotor is mounted on the main generator shaft, and contains the same number of poles as the main generator; therefore it produces the same output frequency.

The PMG is used to provide the power required for initial buildup of the main generator field; it also supplies power for the controls and regulation system.

D-C GENERATOR.–In most older aircraft all electric power was generated as d.c. In most of the newer aircraft no d.c. is generated; the d-c requirements are met by transforming and rectifying the a.c. In some presently operational aircraft, however, the main power generation system provides both a-c and d-c voltages from a common unit. In other aircraft models, a separate generator is used to provide the d-c power required for operation of the d-c components. This method is not common in airborne applications because of the limited number of prime movers (engines) available.

The basic theory of d-c power generators is presented in chapter 18 of Basic Electricity, NavPers 10086-B.

EMERGENCY GENERATORS.–In the event of failure or shutdown of the aircraft's engines or main generators, the electric system becomes inoperative. The aircraft, however, must have electrical power in order to maintain adequate flight control. All naval aircraft incorporate an auxiliary or emergency generator which operates independently of the aircraft engine.

The most common type of emergency generator is the ram air turbine (RAT). It is normally enclosed within the fuselage, being projected into the airstream when its operation is necessary. Driving power for the rotor is derived from the movement of a turbine through the air; it can be operated only in flight or with blast air when on the ground.

Due to its relatively small size, the emergency generator cannot supply the electric loads required for normal operation of the aircraft. Therefore only those systems and equipments considered essential for the maintenance of flight are operable when the aircraft is dependent on the emergency generator.

Because the rotor of the ram air turbine generator turns at a variable speed (dependent on the speed of the aircraft in flight), frequency stability is not so refined as that of the main generators. A governor is usually incorporated to limit rotational speed; the frequency is thus prevented from becoming too high. No solution has yet been found for maintaining operation of the generator when the aircraft speed drops below a certain point. Therefore, in the event of a power-off landing, all electric power and stability control is lost before the aircraft rolls to a full stop.

System Voltage Regulation

Voltage regulators are incorporated in all electric generation systems. Although similar in basic purpose, the configuration and details of operation vary with each type. Basic theory of voltage regulation and regulator devices is presented in chapters 16 (for a.c) and 18 (for d.c.) of Basic Electricity, NavPers 10086-B. A practical 3-phase a-c static voltage regulator, specifically designed for aircraft usage, is shown in simplified form in figure 6-2 and discussed in the following paragraphs.

AT.45

Figure 6-2.–Voltage regulator, simplified schematic.

The voltage sensing circuit of the regulator incorporates a highest phase takeover (HPT) circuit developed specifically for aircraft systems. This circuit permits regulation of the average of the 3-phase voltages during normal system operation and during slightly unbalanced conditions of the system. Large unbalanced load conditions result in large unbalanced voltages. The HPT circuit allows regulation of the highest individual phase-to-neutral voltage. The unit thus incorporates the advantages of both the average voltage sensing circuit and the highest phase voltage sensing circuit.

The output of the HPT circuit is compared with an accurate voltage obtained from a cold cathode voltage reference tube. Any difference between the sensed voltage and the voltage reference causes a current to flow in the control winding of a magnetic amplifier. This amplifier is energized by a single-phase a-c voltage, such as that produced by the permanent magnet generator previously discussed. The current in the control winding determines the current output of the PMG to the magnetic amplifier output circuit. The output of the magnetic amplifier supplies the control winding of the saturable current potential transformer.

If the voltage rises at the generator terminals, the output voltage from the sensing circuit increases. This in turn increases the error signal between the sensing circuit and the glow tube reference, and adds to the current in the control winding of the magnetic amplifier. The increased current tends to increase the magnetic amplifier's output current, which then passes through the control winding of the SCPT and makes it behave more like an air core transformer. This reduces the output power. Since the output power of the SCPT is the input power to the generator field, the terminal voltage of the generator is lowered to its required level.

13272

Power Conversion Devices

In most naval aircraft, the main electric power generation system produces 3-phase a-c power at 400 Hz. All aircraft require various levels and quantities of d-c power, and in many instances a-c power of a different frequency is also required. In these cases, various devices are needed to convert the power from the forms generated into the form required for the specific application. A few important conversion devices are discussed briefly in the following paragraphs.

TRANSFORMER-RECTIFIERS.–The most common conversion device for changing a-c to d-c is the transformer-rectifier. The 3-phase, 115-volt a.c. is reduced in a stepdown transformer and then rectified to produce the 28-volt d.c. required for operation of various relays, lights, instruments, mechanical devices, etc. Specific transformer-rectifier units are discussed in the electrical section of the maintenance instruction manual for each model aircraft; the fundamental theory of transformers is discussed in chapter 16, and the metallic rectifier is discussed in chapter 15, of Basic Electricity, NavPers 10086-B.

INVERTERS.–An inverter is a rotating electromechanical device used to convert low voltage d.c. into a.c. It consists essentially of a speed governed d-c motor, an armature and brush assembly, and a permanent magnet inductor type a-c generator, all within a single unit the armature and the permanent magnet rotor are usually mounted on a common shaft. Figure 6-3 and the following paragraphs are based on the E1616-2 inverter used in the P-3 Orion patrol aircraft.

The d-c motor is of the compound-wound type discussed in chapter 19 of Basic Electricity. Motor speed is controlled by a resistor in series with the ground end of the shunt field. The resistor is cut in or shorted out of the circuit by action of a centrifugal switch mounted on the rotating shaft. Electrical connection to the switch is provided by a brush and slipring arrangement. When the inverter is at rest the switch contacts are closed, and the resistor is shorted out as shown in the top section of figure 6-3 (C).

When line voltage is initially applied (fig. 6-3 (B)), full field strength is developed, resulting in large starting torque. Acceleration is rapid. When rotation begins, the contacts of the centrifugal switch tend to be forced open but are restrained by springs. The upper contact of the switch is restrained by a comparatively weak spring; the bottom contact is restrained by a somewhat stronger spring. At some preset speed (usually 5,000 to 7,000 rpm) the upper switch contact is displaced by centrifugal action, opening the switch (middle section of fig. 6-3 (C)). The short is thus removed from the resistor, field current is reduced, and magnetic flux is weakened. These changes combine to result in armature speed acceleration and increase the centrifugal force on the springs.

At approximately 12,000 rpm the lower contact is also displaced by centrifugal action, making contact with the upper contact (whose movement is limited by the preadjusted screw stop). The resistor is once again shorted out (bottom section of fig. 6-3 (C)), the field strength is increased, and motor speed tends to decrease. The speed does not drop noticeably, however, because the make-and-break action of the centrifugal switch is repeated rapidly with any slight change in rotational speed. This feature provides a high degree of speed stability and minimizes the hunting effect.

The generator section features a permanent magnet rotor, mounted on the same shaft as the rotor of the motor. Rotation of the shaft causes an a-c voltage to be induced into the generator's output windings in the stator. The magnitude of the voltage is determined by the strength of the permanent magnet, the number and position of the turns in the windings, and the rotational speed of the magnet. Output frequency is determined by the number of pole pairs of the rotor and the speed of rotation. Since the inverter provides good speed stability, the output voltage and frequency are fairly well regulated. Filtering and additional regulation are included because of possible effects of the load on the line voltage.

The inverter's output frequency and voltage should be checked periodically to assure that they are within prescribed limits. Should adjustment be required, notify the electrical shop since adjustment of inverters is a responsibility of the AE rating.

DYNAMOTORS.–A dynamotor is a rotating electromechanical device used to change (usually,

(B) SIMPLIFIED SCHEMATIC

(C) CENTRIFUGAL SWITCH OPERATION

AT.46

Figure 6-3.–E1616-2 inverter. (A) Cutaway view; (B) simplified schematic; (C) governor contact operation.

to increase) the level of a d-c voltage. It is essentially a d-c motor and a d-c generator mounted or wound on a common form and shaft, and contained within a single housing. A single stationary field is used to provide the magnetic field for both the motor section and the generator section. The armature consists of two sets of rotor windings wound on a common core mounted on the rotating shaft; the two sets of rotor windings are connected to separate commutators. The motor section serves to produce the driving force; the generator section produces a d-c output whenever the shaft rotates.

Although dynamotors were quite prevalent in older aircraft and electronic systems, they are no longer in common usage.

FREQUENCY CHANGERS.–When a-c voltages of a frequency different from that produced by the main generator are required, suitable motor-generator combinations are used. Main electric power frequency is usually 400 Hz; many aircraft provide a 60-Hz source for test equipment and an 800-Hz source for certain instruments or components.

System Protection

The aircraft electric system incorporates circuits designed to protect the system from damage which could result from malfunction or nonoperation of components in the generation system. Protection requirements and system

CT943274

components vary in different model aircraft, so the circuits are not standardized in configuration. This discussion is based on functional application rather than on operating theory.

OVERVOLTAGE.–In overvoltage protective circuits, a relay deenergizes the system when the line voltage exceeds preset limits. In elaborate system, a "highest phase takeover circuit" and a "reactive biasing circuit" are incorporated to provide added protection. Line voltage is sensed and compared with a reference voltage. If the line voltage is too high, and remains excessive for a preset time interval, the protective circuit assumes control and removes the generator from the line.

UNDERVOLTAGE.–The undervoltage relay removes the generator from the line whenever the system voltage drops below a preset limit; sensed voltage is compared with the same reference as that used in the overvoltage protective circuit. Thus the system is protected whenever the voltage supplied to the line is either above or below the narrow range established by the biasing of the relays.

PMG TRANSFER.–This circuit is used in generation systems in which a permanent magnet generator is used to furnish power for the generator controls. If a malfunction occurs in the PMG (or its leads to the control panel), the source of control power is shifted to one of the phases of the main generator. Shifting of power sources is accomplished without interruption by operation of the permanent magnet generator control transfer relay. Once the system has become deenergized, however, the main generator cannot be built up again using the failed PMG.

DIFFERENCE CURRENT.–This circuit is used in paralleled multigenerator systems where the load is evenly distributed between the generators. As soon as the circuit detects an imbalance in excess of allowable limits, a thermal time delay is initiated. If the unbalanced condition persists, the thermal delay relay opens and locks the bus tie contactor out of the system. The individual generators then operate as isolated systems, each supplying its own loads.

SELECTIVE EXCITATION.–This circuit operates in conjunction with the overvoltage and undervoltage relay circuits in paralleled multigenerator systems. If one generator becomes overexcited for any reason, it normally produces an overvoltage and should trip the overvoltage relay for that particular generator. The function of the overexcitation protection circuit is to insure that the overexcited generator is disabled before the malfunction can trip out the relays in an unfaulted generator. Overexcitation is sensed and a signal is developed and routed to each of the overvoltage relays, decreasing the trip point on the overvoltage relay of the faulty circuit and increasing the trip point of the others. Thus the faulty generator is removed from service, while the others remain in operation.

The underexcitation protection circuit functions in a similar manner, except that it biases the undervoltage relay rather than the overvoltage relay. In both cases, the biasing changes result in tripping the faulty generator. The circuit allows tripping of the other generators only if the removal of the faulty generator fails to correct the overvoltage.

PARALLEL OPEN PHASE.–If an open phase develops in one of the generators of a paralleled multigenerator system, excessively high circulating currents may result. These currents could cause erroneous tripping of the overvoltage relay in an unfaulted generator. A parallel open phase relay senses any open phase, and a signal is routed to the relay. When the relay operates, the faulty generator is removed to lower the circulating currents and prevent tripping of the unfaulted generators.

ANTICYCLING.–Systems which are protected by disabling relays are inherently subject to cycling operation. That is, when the operation of a relay removes a faulty component from the line it also removes the cause of its own initial operation; therefore the relay returns to its normal condition and the faulty component is returned to the circuit. If the faulty condition still exists, it trips the relay again, and starts another cycle. Anticycling protection consists of a lockout relay that operates to lock in an open position through a set of its own contacts. Thus the faulty circuit cannot cycle itself–the system remains inoperative until the tripped generator control switch is turned to the OFF position and then returned to the ON position.

External Power

Essentially all aircraft have provisions for application of electric power from an external

13275

source for starting the aircraft engines and/or for ground servicing and maintenance without operating the engines. This power, while not generated within the aircraft, is part of the overall electric system of the aircraft. It must be in all aspects compatible with the power generated within the aircraft. Under no circumstances may the internal and external power be utilized at the same time. This is one of the functions of the distribution system, which is discussed briefly below. (The equipments used to supply power in the external mode of the electric system are discussed briefly in a later portion of this chapter.)

Distribution System

Once the electric power has been generated and some of it transformed, it must be distributed to the various components and equipment where it is to be used. In a simple system, with comparatively few equipments and requiring only a single form of electric power, a simple distribution system could be used. In modern naval aircraft, however, with the complex electrical and electronic installations requiring many forms of power, an extremely complex distribution system is required.

Each model aircraft has different electrical requirements; therefore, each distribution system must differ from all others in accordance with individual requirements. The following discussion is presented to illustrate general principles and considerations, rather than to describe any particular system.

The major area of difference between distribution systems of different model aircraft lies in the switching arrangement used to change electric loads from one source to another in the event of a malfunction.

Long range patrol aircraft normally carry a flight engineer as part of its operating flight crew. The flight engineer is responsible for monitoring the operational status of many different systems within the aircraft. In some aircraft he is responsible for distributing individual electric loads among the various sources so as to provide for essentially balanced loads. He is usually responsible for recycling failed systems when it is assumed that the fault has been corrected. Interceptor and other carrier-based aircraft usually do not have a separate flight engineer. The distribution system for these two systems must be quite different in details, even though they may both incorporate all the same basic requirements and capabilities for load distribution.

P-3 ELECTRIC SYSTEM

This aircraft represents an outstanding example of versatility and flexibility in electric systems. It also illustrates several concepts which will probably find general application in future versions of long range aircraft.

The P-3 "Orion" is a land-based, four-engine, long range patrol type aircraft used primarily for ASW operations. Its electric system includes three main generators, which are driven by engines No. 2, 3, and 4. The No. 1 engine is not used in the generation of electric power. Engines No. 2 and 3 operate at a constant speed regardless of power settings, therefore a separate CSD unit is not required—the frequency regulation requirement is supplied by the engine itself. Under normal conditions of operation the entire electric load is supplied by generators driven by engines Nos. 2 and 3. Engine No. 4 is identical to the others. The generator driven by engine No. 4, however, is driven through a 2-speed gearbox. This feature permits the generator to supply power while the aircraft is on the ground and operating with decreased engine power. During normal operation the No. 4 generator is not feeding the loads, but is in a standby condition ready to assume the load of either generator if necessary.

The main generators are statically excited, statically regulated, and controlled from power produced by a PMG mounted on the generator shaft. Power produced by each generator is 117/202-volt, 3-phase, 400 Hz a.c.; the generators are not paralleled. Each has a capacity well in excess of its normal operating loads. Except under conditions of severe icing, only a slight reduction in total load is required for continued operation with a single generator supplying the entire load. To supply deicing power, however, a more drastic reduction in operating loads is needed.

Each generator is provided with undervoltage, overvoltage, differential current, and frequency protection. In addition, a failure warning light is connected to a "run strip" in

13276

the generator rotor which indicates any rotor-to-stator short. For generator No. 4, a "disengage" light is connected to high temperature and low pressure sensors in the two-speed gearbox oil system.

Failure of one generator causes no interruption of power because the standby generator automatically and immediately assumes the load normally supplied by the failed generator. "Generator Off" lights are installed for each generator to advise the flight crew when the unit is not available for operation.

Reverse phase protection of the external power connection prevents the power relay from closing if the phase rotation is incorrect.

Power produced by the generators is supplied to a main load center which houses the exciters, regulators, and control and protection devices for each generator. (See fig. 6-4 (A).) The same load center also contains the power transfer relays, the main power distribution buses, two transformer-rectifiers, and miscellaneous circuit breakers, switches, relays, and minor items of equipment. (A third transformer-rectifier is located in the forward load center.)

The power transfer relays are so connected that any of the generators can supply power to either or both buses. Additional relays and wiring (called the "runaround" circuit) permit bypassing the normal transfer relays and distribution feeders, thus supplying power from anyone of the three generators to the essential a-c bus. The three transformer-rectifiers are so connected that the necessary d-c control power is available for all possible connections of the a-c buses. The buses and the switches and relays controlling their connections are indicated in figure 6-4 (B). Reference to this figure should be made at frequent intervals throughout the remainder of this discussion.

Operation of the system during normal flight conditions is entirely automatic. The crew needs only to monitor the circuit breaker and control panels at the load centers for any indication of malfunction.

Control of the system is also automatic during ground operation, except switching to and from external power. A light is provided in the flight station and at the external power receptacle to indicate when external power is being used.

During engine speed changes, the No. 4 engine speed should be reduced first and the No. 4 generator will temporarily be shut off by the frequency sensing relay while the speed is changing and the gearbox shifts; it will then come back on and be available to pick up the aircraft loads when generators No. 2 and 3 drop out due to underfrequency (as a result of reduced engine speed). The speed of engines No. 2 and 3, on the other hand, should be increased before No. 4 and will automatically take over their respective buses when they reach normal operating speed. Power interruption during speed changes is thus limited to the time (30 milliseconds, approximately) required for a normal bus transfer.

Temporary loss of all generator power requires that a source independent of the engine's generators be made available for starting the aircraft engines. Conditions of flight and the size of the essential flight loads are such that the use of a ram air turbine generator for emergency power has been deemed impractical. A 24-volt, 11-ampere-hour, lead-acid storage battery is provided to supply power for ignition and for flashing the field of the generator. (Engine rotation results from windmilling propellers.) Starting load requirements also include a.c., which is supplied by a battery-driven 100-ampere-hour inverter. The inverter and its loads are connected through a "start essential" bus; switching control is through the start selector switch. The bus switches to the battery if no other source of d-c power is available.

To provide for prolonged loss of generator power, a bypass and load monitoring system has been provided. This system provides for three levels of emergency, as follows:

1. BUS A and BUS B switches, when actuated to the OFF position remove all loads except those classed as essential.
2. Actuating the essential bus switch to the OFF position, in addition to the above, removes all but the minimum necessary flight loads.
3. Lifting the guards and turning all three generator switches to the OFF position removes ALL loads on the aircraft except a turn-and-slip indicator, two cockpit utility lights, emergency warning indicator, and the d-c control supplied by the battery.

13277
13276

AT.47

Figure 6-4.–Electric power distribution in P-3, simplified.

13278

One additional feature of many new models of aircraft, including the P-3, that deserves discussion is the deletion of ammeters and voltmeters from the main control panel. The case for the installation of meters is that an experienced crewmember can gain an appreciable amount of information useful in diagnosing system problems by carefully observing the meters. However, in agreement with the present Naval Air Systems Command design policy, and based on the following reasoning, no voltmeters or ammeters are installed in the P-3 aircraft.

1. The value of meters is basically for maintenance purposes. The voltage is automatically regulated and no adjustment is available to the flight crew.

2. The meters used in conventional control panel installations are not good maintenance instruments.

3. It is not practical to provide voltage and current indications for all points in the system that need to be checked in maintenance.

4. The information obtained by the flight crew from meters may do more harm than good in that it is frequently misinterpreted.

NOTE: An auxiliary power unit (APU) is installed in some P3 aircraft. When the APU is installed, the battery in the nosewheel well is changed from a 24v, 11-ampere-hour type to a 24v, 34-ampere-hour type. On newer aircraft incorporating a starting capability, the 2-speed gearbox is removed from the No. 4 engine.

The APU is gas turbine-driven, providing compressed air for engine starting and air conditioning; it also provides mechanical power to drive a 60-kva Bendix brushless generator whose electrical output is used for ignition during engine starting, ground operation of all aircraft electrical and electronic circuits, and emergency electrical power during flight (possible only on those units that have in-flight starting capability incorporated). APU controls are mounted on the auxiliary power unit control panel which is on the center overhead panel in the flight station.

F-4B ELECTRIC SYSTEM

The F-4B was selected for discussion in this chapter because it offers an example of the continuous process of improving the reliability and simplifying operation of the overall electric system.

The F-4B "Phantom II" is a carrier-based, two-engine, high speed, high altitude, jet interceptor type aircraft. The engines operate at varying speeds according to power settings; therefore a separate CSD unit is needed to provide the generator with a constant speed of rotation. The main power generation system produces a well regulated 115/200-volt, 3-phase, 400-Hz a.c. Part of the a-c power is transformed and rectified to 28-volt d-c power. The system utilizes the static excitation and regulation systems, and incorporates numerous protective features. Main a-c buses are operated in parallel for improved frequency regulation and equalized load distribution, with provision for individual operation in the event of bus tie failure.

New versions of the basic aircraft have incorporated an automatic CSD disconnect system. In older models, the engine was shut down whenever overheating of the generator or CSD unit was indicated. This required operation on single engine and attempted air-starts of the secured engine, with many aborted missions and emergency alerts. With the new unit installed it is no longer necessary to secure the engine, unless the cause of overheating is low oil supply in the engine-CSD-generator system (all three units use a common oil supply for cooling).

Another recent modification, the use of brushless generators, has resulted in increased power output ratings coupled with improvements in the control and regulating components. The modification has decreased total weight, improved reliability, and lowered maintenance requirements.

In early versions of the aircraft, damage to the transformer-rectifiers was frequently caused by the application of external power with reversed phase, improper voltage or frequency, or some other defect. A fuse has been installed in the external power circuit to protect the external transformer-rectifier from damage when any parameter of the external power falls outside tolerances.

A problem common to many aircraft involves the ram air turbine (RAT) emergency generator. In early versions of the Phantom II, the emergency generator supplied hydraulic power in addition to the electric power, for use

13279

when both engines were inoperative. This combined requirement limited the RAT to fairly high flying speeds and resulted in the loss of emergency power prior to touchdown in the dead-engine emergency landing. Recent modifications have allowed removal of the hydraulic provisions from the RAT. Improvements to the turbine and its associated generator have permitted the production of adequate emergency electric power at a much lower speed. The newer aircraft can maintain emergency electric power with a speed below that of normal touchdown. Since power decreases rapidly after touchdown, a cutout switch has been installed in the landing gear system. This switch removes the emergency generator from the line upon touchdown and protects the essential bus equipments and components from the effects of low voltage and frequency.

Improvement of the emergency generator system is expected to bring about changes in the essential bus system. The extent and exact nature of these changes is not known at the time of this writing. It is also expected that the parallel operation feature of the main a-c system will be eliminated in an effort to simplify the overall operation of the system.

CIRCUIT PROTECTION AND CONTROL DEVICES

The electric system of an aircraft is protected from damage and failure by fuses, current limiters, and circuit breakers. Control and distribution of power is accomplished by the use of switches and relays. Each of these components is available in many styles and sizes, some of which are ideally suited for use in aircraft while others are limited to use in shop installation. The following section presents a brief discussion of these components.

FUSES

Fuses provide a controlled, intentionally weakened link in an electric circuit. It serves as a safety device in the event of undesired overloads. Fuse sizes are available with ratings of from two milliamperes to several hundred amperes; fuses of most ratings are available for normal, slow-action or fast-action operation.

A fuse is a heat-sensitive, heat-operated device. When operated at rated current it consumes electrical power and dissipates this power in the form of heat. Under normal operating conditions, the dissipated heat is not sufficient to cause the unit to fail; however, when the fuse is operated above the normal current rating, the overload current generates additional heat which melts the fusible element.

Voltage Rating

A fuse can be operated at any circuit voltage, if it is mounted in a sufficiently well insulated holder (as long as the fusible element is able to fail without suffering arc damage). When a fuse fails due to excessive current, the full circuit voltage appears across the open fuse; if inductance is present in the circuit, a surge is generated which may cause a destructive arc to be formed within the fuse. Under these conditions, intense heat and pressure develop and the fuse may literally explode.

Fail-Time Characteristics

The fail-time characteristic of a fuse depends on the percent of rated current and the thermal inertia of the fuse. Overload currents (currents larger than the maximum value for which the fuse is rated) when flowing through a fuse, heat the element beyond normal capacity; after a period of time, the fusible element fails.

Fuse elements with a large thermal inertia increase the length of time before failure. Fuses containing such elements are known as slow-acting, slow-blow, or time-delay fuses. Slow-action fuses are constructed with a compound element; a thermal cutout and a fusible link that melts on short circuits or very high overloads. Small, light fuse elements reduce the thermal inertia and therefore are faster acting. This type of fuse is known as a fast-action fuse and is used principally for the protection of sensitive instruments.

In the selection of a fail-time characteristic, both the steady state and the transient or surge currents are considered. If currents of 200 to 400 percent of normal can be tolerated for periods of 10 seconds, a slow-acting fuse is specified. If the circuit requires immediate

13280

protection for any current above normal, a fast-acting fuse is specified. If the current must be limited to 200 percent of the rating for periods less than one second, then a normal, or medium, fail-time characteristic is specified. (See fig. 6-5.)

When possible, a fuse should be operated at about 75 percent of its rated value; this provides a good balance between protection and reliability.

Vibration Resistance

Fuse protection for equipment subject to vibration can be provided by special vibration-resistant construction. This type of fuse has a spring formation, with winglike extensions which bear on the inside wall of the glass body, to decrease vibration of the fuse element. For slow-action fuses, a different construction, consisting of a compound spring and link structure, is used. On moderate overloads, as the compound element reaches the melting point, the spring pulls away from the link; on short circuits, the link fails.

Identification Coding

Fuses and their corresponding fuse holders are numbered according to a standardized system for easy identification. The numbering system is illustrated and explained in figure 6-6; some actual fuses are shown in figure 6-7.

Fuse Holders

The most common class of fuse holders used in Navy equipment is the post type holder shown in figure 6-7. It may be a screw-in or a bayonet type, both of which are securely mounted to the chassis or front panel of the equipment. The purpose of the holder is the same, regardless of type– to hold the fuse securely with good electrical connection and physical stability for protection from mechanical vibration and electrical short circuit.

AT.48

Figure 6-5.–Fail-time characteristics of fuses.

Care should be used to insure that the fuse is of a physical size compatible with the holder. Fuses which are too small allow physical movement and arcing, resulting in a blown fuse or a damaged holder; fuses which are too large may cause cracking or breaking of the holder. Force should never be applied to either the fuse or the holder, since both these are quite delicate.

Post type fuse holders are normally series-connected in the line, with the end connection to the power source and the center connection to the load. When connected in this fashion, the equipment is protected in the event of a broken holder–a short circuit from fuse holder to chassis ground will result in a blown fuse and excessive current will not flow. Reversed connections will not furnish this protection. Connection is normally made by solder connection, although some fuse holders are connected by use of the screw and lug method.

Current Limiters

Devices somewhat similar to fuses, called current limiters, are used in aircraft circuits that carry high currents. (See fig. 6-7.) The current limiter consists of a copper link of carefully predetermined sections. The sections melt when abnormally high currents start to flow. The melting sections have a high arc resistance to keep the circuit current within the capacity of the limiter. If the excessive current is only a temporary surge, the melting ceases and the circuit continues to operate as if no abnormal current had been present. Repeated applications of excessive current, or uninterrupted application for a period of several seconds, melt through the sections and cause the limiter to "blow" in the same manner as a fuse.

CIRCUIT BREAKERS

In modern naval aircraft, circuit breakers have replaced fuses as the main circuit protec-

tion device for most of the wires and cables making up the electrical system. The circuit breaker is designed to open the circuit under short-circuited or overloaded conditions without injury to itself. Thus, it performs the same function as the fuse, but has the advantage that it is capable of being reset and used again. Circuit breakers are rated in amperes and volts.

There are three basic types of circuit breakers (thermal, magnetic, and thermomagnetic), but the following discussion is directed mainly toward the thermal type because it is more generally used. Circuit breakers are divided into three categories—the pushbutton reset type, the toggle type, and the automatic reset type (sometimes called a circuit protector).

The pushbutton reset type consists of a bimetallic, thermally actuated, spring loaded device which closes two electrical contacts when set. This is shown in figure 6-8. An excessive current through the device causes an uneven expansion of the bimetallic mechanism (thermal release) which releases a trigger escapement and permits the spring loading to separate the contact members.

A visual indication of the automatic opening is provided by causing the pushbutton to move to an easily noticed "tripped" position. In this position the button is fully extended and the white ring plus the inner red section of the button is showing. The latest type of pushbutton breakers have a pullout feature which permits manual opening of the circuit, but this type should not ordinarily be used as a switch.

Another type of circuit breaker uses a toggle lever instead of the pushbutton. It operates in the same manner as the previously discussed breaker, with the exception that the tripped condition is indicated by the toggle lever being in the OFF position. This type of circuit breaker has the apparent advantage of also being usable as a switch.

Manual resetting of the circuit breaker may be accomplished by means of the actuator (either pushbutton or toggle lever) whenever the bimetallic thermal element cools sufficiently for the trigger to engage its latching mechanism. In connection with resetting, there are two classifications for circuit breakers; namely, trip-free and non-trip-free.

The non-trip-free circuit breakers can be prevented (by the operator's action) from tripping even though a tripping condition exists. This should be done only in an emergency; since this action is apt to change the calibration, the breaker should be replaced as soon as conditions permit. This type breaker is no longer being installed in new aircraft; however, it is still found on some older models.

18282

AT.50

Figure 6-7.–Aircraft fuses and fuse holders, typical examples.

In the trip-free class, the contacts cannot be kept closed by holding the actuator in the closed (or reset) position as long as an overload condition persists which would otherwise cause normal tripping.

A disk type thermal circuit breaker is shown in figure 6-9. This breaker consists of a conductive bimetallic snap-acting disk which bridges two electrical contacts. When this disk is heated by the excess current through it, it snaps to the reverse position, opening the contacts and breaking the circuit. In circuit breakers having low ratings, a resistance wire is inserted; current through this wire provides the heat necessary to snap the disk. These breakers are reset by pressing a button, restoring the disk to its original position. When circuit breakers of this type are closed, they cannot be reopened manually. They are also nonindicating; that is, the position of the breaker (open or closed) cannot be determined by visual inspection.

The automatic reset type circuit breaker is similar to the bimetallic disk type just described, except that it has no reset pushbutton; it resets itself automatically. After a short time, when the disk has cooled sufficiently, it will bend back and close the circuit, resetting itself. If a constant overload exists, the breaker will intermittently break the circuit.

AT.51

Figure 6-8.–Thermal circuit breaker.

13283

AT.52

Figure 6-9.—Thermal circuit breaker (disk type).

Another type of circuit breaker is the switch toggle variety based on magnetic instead of thermal operation. This type can be made to open almost instantly when more than the rated current flows in the circuit. An electromagnet is placed in series with the spring-loaded contacts, and the contacts are mounted so that an armature acts as a latch to hold them closed. When an excess current flows, the armature is pulled toward the electromagnet, releasing the contacts and opening the circuit. To reset the circuit breaker, the contacts are closed manually and the spring-loaded armature returns to its normal position.

SWITCHES

A switch may be described as a device used for making, breaking, or changing connections in an electrical circuit. Switches are rated in amperes and volts; the rating refers to the maximum allowable voltage and current of the circuit in which the switch is to be used. Since it is placed in series, all the circuit current will pass through the switch; because it opens the circuit, the applied voltage will appear across the switch in the open circuit position. Switch contacts should be opened and closed quickly to minimize arcing; therefore, switches normally utilize a snap-action.

Many types and classifications of switches have been developed. A common designation is by the number of poles, throws, and positions. The number of poles indicates the number of terminals at which current can enter the switch. The throw of a switch signifies the number of circuits each blade or contactor can complete through the switch. The number of positions indicates the number of places at which the operating device (toggle, plunger, etc.) will come to rest. Figure 6-10 presents the schematic diagram of some typical switches.

An example of the switch position is a toggle switch which comes to rest at either of two positions, opening the circuit in one position and completing it in another. This is called a two-position switch. A toggle switch which is spring loaded to the OFF position and must be held in the ON position to complete the circuit is called a single-position switch. If the toggle switch will come to rest at any of three positions, it is called a three-position switch.

Another means of classifying switches is the method of actuation; that is, toggle, pushbutton,

AT.53

Figure 6-10.—Schematics of commonly used switches.

13284

precision, and rotary types. Further classification can be accomplished by a description of switch action such as on-off, momentary on-off, on-momentary off, etc. Momentary contact switches hold a circuit closed or open only as long as the operator deflects the actuating control.

Manually Operated Switches

One of the most common types of aircraft switches is the toggle. Toggle switches have their moving parts enclosed. A double-pole, double-throw, on-off-on toggle switch is shown in figure 6-11. These switches have many uses and are used especially for applying power to various circuits. They are often provided with a luminous tip on the lever so as to be visible in the dark.

Pushbutton switches have one or more stationary contacts and one or more movable contacts. The movable contacts are attached to the pushbutton by an insulator. These switches are usually spring loaded and are of the momentary contact type. They have many uses, such as indicator light checks and circuit reset. The push-on and push-off type switch is seldom used in naval aviation.

A rotary selector switch may perform the functions of a number of switches. As the knob of a rotary selector switch is rotated, it opens one circuit and closes another. This can be seen from an examination of figure 6-12. Some rotary switches have several layers of wafers. By adding wafers, the switch can be made to operate as a large number of switches. Ignition switches and voltmeter selector switches are typical examples of this type.

Mechanically Operated Switches

Mechanically operated switches are used in many types of installations, such as radar limit switches for antenna throw, as interlock switches to disable the power to equipment when removing the case, and as communication transceiver control box switches. Many of these are the precision, snap-acting switches found in all aircraft. They are widely used because of their small size, light weight, and excellent dependability. (The term Micro switch, although frequently used in referring to all switches of this type, is a trade name for the switches made by the Micro Switch Division of the Minneapolis Honeywell Regulator Company.)

These switches will open or close a circuit with a very small movement of the tripping device (1/16 inch or less). They are usually of the pushbutton variety, and they usually depend on one or more springs for their snap action. For example, the heart of the Micro switch is a beryllium copper spring, heat-treated for long life and unfailing action. The simplicity of the one-piece spring contributes to the long life and dependability of this switch. The basic Micro switch is shown in figure 6-13.

AT.54

Figure 6-11.–Toggle switch.

AT.55

Figure 6-12.–Rotary selector switch.

13285C1

AT.56

Figure 6-13.–Micro switch.

The versatility of the snap-action switch is indicated in figure 6-14, which shows how the basic switch may be used with different type enclosures and actuators. The particular type of switching unit used depends upon the function it is to perform and upon environmental conditions. Figure 6-14(A) shows a lightweight aluminum enclosure which may contain one or more plastic-enclosed basic switches. The plastic enclosure provides electrical insulation between the housing and the live electrical parts, support for the terminals, and a dusttight box around the electrical contacts.

Figure 6-14 (B) shows one of the various types of switch actuators used with basic switches when complete enclosures are not needed. They provide a means for protection and mounting of the switch. They relay the operating motion from a cam or slide to the basic switch in a way that assures long life and dependability. Figure 6-14 (C) shows a toggle switch which uses one or more of the basic subminiature switches. These subminiature switches are smaller than the conventional Micro switch and are finding wide use in various switching arrangements.

Pressure-operated switches usually have Bourdon tubes, syphons, or diaphragms against which fluid operates to actuate the switch. Some low-frequency transmitters use pressure switches to reduce transmitter power at high altitude (and thus prevent arcing).

Thermal switches usually incorporate a bimetallic sheet that bends or snaps at a desired temperature to actuate the switch. They are used extensively as circuit breakers and also find application in controlling the igniter circuit on heaters, and in operating signal lights at critical temperatures.

Maintenance

While the switch itself is relatively simple to check, it sometimes offers difficulty in maintenance because of its location in inaccessible places. After a visual inspection of the connections and the switch, a continuity test will indicate any malfunctions. When the switch mechanism is found to be defective, it normally is not repairable and therefore should be replaced.

AT.57

Figure 6-14.–Snap-action switching units.

13286

When enclosed switches are used, failure to seal properly around cable openings is the most common cause of trouble. Altitude changes permit "breathing" of moist air into enclosures within the switch enclosure. The condensation can short across the switch terminals, or it can corrode the switch actuators and make them inoperative. This problem can be eliminated by carefully sealing the openings, or by using hermetically sealed switches. (Hermetic sealing will also prevent dust and dirt from reaching the contacts and thereby reduce the possibility of high resistance shorts and open circuits.)

Some switches are damaged during installation, particularly those with plastic housings. Proper care in installing or replacing plastic-enclosed switches will help to eliminate this type of trouble.

Some switch assemblies are equipped with adjustments which enable them to operate at a preset temperature, pressure, position, etc. Caution should be exercised in making these adjustments; if they are not accurate, damage to the switch or to the equipment can result.

RELAYS

Types

Relays are electrically operated control switches, and are classified according to their use as control relays or power relays. Control relays are usually known simply as relays; power relays are called contactors. Power relays control the heavy power circuits of the aircraft electric system.

The function of a control relay is to take a relatively small amount of electrical power and use it either to signal or to control a large amount of power. Where multipole relays are used, several circuits may be controlled simultaneously.

The use of relays saves space and weight in the aircraft by permitting the use of small switches at remote control stations. The relays permit the operator to control large amounts of current at other locations in the aircraft, and the heavy power cables need to be run only to the point of use. Only lightweight control wires are connected to the control switches. Safety is also an important reason for using relays, since high power circuits can be switched remotely without danger to the operator.

Control relays, as their name implies, are frequently used in the control of low power circuits or other relays, although they also find many other uses. Electron tube plate current relays can control the larger currents necessary to operate electrical devices. In automatic relaying circuits, a small electric signal may set off a chain reaction of successively acting relays, which then perform various functions. Control relays can also be used in so-called "lockout" action to prevent certain functions, such as the firing of rockets, from occurring at the improper time. Electrical operations which must not occur simultaneously can be "interlocked" by control relays. Another important function of control relays in aircraft equipment is for "sensing" undervoltage and overvoltage, reversal of current, excessive currents, phase and amplitude, polarity, etc.

Another possible classification of relays is open, semisealed, or sealed. Semisealed relays have protective covers which are installed with gaskets to prevent entrance of salt, dust, and foreign material into the contact or mechanism area. These relays are still considered satisfactory for certain applications in present-day aircraft.

For most applications in today's high altitude, high speed aircraft, however, it is necessary to go beyond the protection offered by semisealed relays. When such relays are used, quick changes in altitude, humidity, and temperature can cause condensation of moisture within the unit. Subsequent low temperatures may then freeze the moisture on the contactor.

Hermetically sealed relays were developed to answer the demands of most modern aircraft equipment. A true hermetic seal is generally considered one that is metal to metal or glass to metal. Plastic or plastic-rubber type gasketed seals are not generally considered true hermetic seals. However, both semisealed and hermetically sealed relays are used. In some applications a gasket sealed relay may be adequate, but the true hermetically sealed type is generally considered to be more desirable. In addition to being independent of altitude changes, the hermetically sealed relay also has the advantage of being protected from improper adjustments.

13287

Operation

In general, the basic components of a relay are the coil (or solenoid), the iron core, the fixed and movable contacts, and the mounting (and if sealed, the can). A manual switch, limit switch, or other small control device starts and stops the flow of current to the coil. The flow of electric current through the coil creates a strong magnetic field around and within the coil. This magnetic field moves a clapper or plunger which completes the magnetic circuit. Figure 6-15 (A) shows a basic single coil clapper type relay. The dashed lines indicate the magnetic lines of flux. For a more complete analysis of magnetic theory and basic relay operation, see Basic Electricity, NavPers 10086-B.

The second basic type of relay is the rotary (fig. 6-15 (B)). Although this type of construction is not as common as the clapper type, the rotary type has greater vibration and shock resistance than the others. Their main disadvantage is that they are somewhat sluggish and require higher operating power. The rotary relay operates on the principle of an electric motor, but turns through only a small angular arc. The problem of hanging contacts on such a mechanism is a difficult one, and therefore the use of these devices is limited. When used with standard wafer switch assemblies, this type of relay provides a means for assembling a switching device of any degree of complexity.

Some relays operate from an a-c supply. A-c relays depend upon the same fundamental principles as the d-c relay; that is, magnetic fields. When alternating current is applied to an electromagnet, the current passes through zero twice every cycle. Since the pull on the armature is proportional to the current through the electromagnet, the armature tends to open every time the current nears zero, causing the relay to chatter. To prevent this, shading coils (sometimes called shaded poles) are used.

A shading coil consists of a copper band or stamping which is short-circuited and embedded around part of the electromagnet pole face. By being placed around part of the pole face, it acts as a shorted transformer secondary. The current in the main coil lags the applied voltage by approximately 90°; the flux is in phase with the current. The voltage of the shading coil is an induced voltage, and it lags the current in the main coil by 90°. Since the shading coil acts like a shorted secondary (resistive), the current in the shading coil is in phase with the induced voltage. Therefore, the magnetic field of the shading coil lags the magnetic field of the main coil by 90°. Flux continues to exist in the electromagnet even when the main coil current becomes zero; thus chattering is prevented.

Relay contacts are arranged in many different forms. Usually the number and sequence of switching operations to be performed dictates the contact arrangement.

It is often desirable to introduce time delays by use of relays. One method is to use a thermal relay for a time delay. The operation of this type relay is similar to that of the thermal circuit breaker, with the exception that it closes the circuit (rather than opens it), when heated. Due to the simplicity of the mechanism, it can be made very small and can be hermetically sealed, making it ideal for use in aircraft. Because the thermal relay is activated by heat, it can be used on either a.c. or d.c.

AT.58

Figure 6-15.—Basic types of relays.

Maintenance

The relay is one of the most dependable electromechanical devices in use; but like any other mechanical or electrical device in aircraft equipment, relays occasionally wear out or become inoperative for one reason or another. Should an inspection determine that a relay is defective, the relay should be removed immediately and replaced with another of the same type. Care should be exercised in obtaining the same type replacement because relays are rated in voltage, amperage, type of service, number of contacts, continuous or intermittent duty, and similar characteristics.

1328

Relay coils usually consist of a single solenoid. If a relay fails to operate, the coil should be tested for open circuit, short circuit, or ground. An open coil is a common cause of relay failure.

The formation of film on the contact surfaces of a relay may be considered as another principal cause of relay trouble. Although film will form on the contacts by the action of atmospheric and other gases, grease film is responsible for a lot of contact trouble. Carbon formations, caused by the burning of a grease film or other substance (during arcing), also can be troublesome because carbon forms rings on the contact surfaces. As the carbon rings build up, the relay contacts are held open.

When current flows in one direction through a relay, the contacts may be subjected to an effect called "cone and crater." The crater is formed by the transfer of the metal of one contact to the other contact, the deposit being in the form of a cone.

Some relays are equipped with ball shaped contacts. In many applications this type of contact is considered superior to the flat surface. Dust or other substances are not as readily collected on a ball shaped surface. In addition, a ball shaped contact can penetrate film more easily than a flat contact. When cleaning or servicing ball shaped relay contacts, extreme care must be taken to avoid flattening or otherwise altering the contact's rounded surfaces.

Under normal operating conditions, most relay contacts spark slightly; however, this type of sparking must not be confused with the spitting and arcing which causes burning and pitting of the contacts.

All relays require maintenance and care. Contact clearances or gap settings must be maintained in accordance with the relay's operating specifications. Relay contact surfaces must be kept clean and in good operating condition.

For detecting potential relay trouble during preventive maintenance, the following guides are suggested: Check for charred or burned insulation on the relay and for darkened or charred terminal leads coming from the relay. Both of these indicate overheating. If there is even a slight indication that the relay has overheated, it should be replaced with a new relay of the same type. Overheating is sometimes caused by the power terminal connectors not being tight enough; screw connections should always be checked during preventive maintenance.

NOTE: Life of relays may be increased by removal of a light film buildup with recommended spray contact cleaner and lubricant.

Extreme care should be taken in removing and replacing covers on semisealed relays. The entry of dust or other foreign material may cause contact discontinuity. When the relay is installed in a position where there is a possibility of contact with fuel fumes, extra care should be taken with the cover gasket. Any damage to the gasket, or incorrect seating of the gasket, increases the possibility of igniting vapors.

AUXILIARY POWER SOURCES

The electric power requirements for starting and servicing modern aircraft are very high. Even in those aircraft which have batteries installed, routine servicing and operational testing of the electronics system require that either the aircraft engines be operating or that an external source of electric power be used.

There are many auxiliary power units (APU's) available for supplying electric power to the aircraft for engine starting, ground servicing, and operational testing. External power receptacles are mounted on all aircraft to provide a means of connecting the external sources to the aircraft.

Some aircraft are also furnished with an airborne auxiliary powerplant (APP) installed aboard or attached externally to the aircraft. The auxiliary powerplant usually consists of an independently operated gasoline engine or turbine which drives a generator. The generator supplies power to the electric system on the ground and in the air. Although the airborne auxiliary powerplant is not capable of supplying the entire load requirements for normal operation of all equipment, it does have the capacity to furnish limited loads for ground servicing or for emergency use in flight.

This section presents a brief discussion of batteries, ground- and ship-based auxiliary power units, airborne auxiliary powerplants, and the main power sources normally found in aircraft hangars and on carrier flight decks.

BATTERIES

The function of the aircraft storage battery is to provide an emergency source of electri-

13289

cal power for operating the electrical systems of an aircraft. The battery also functions in such a manner that it eliminates the commutator ripple produced by the d-c generator. During normal aircraft operation, the generator supplies the primary source of electrical energy, and maintains the battery in a charged state. The battery supplies power to the aircraft only when the speed of the engine or gererator drive system becomes so slow that the generator's output voltage falls below the battery voltage.

The battery is the emergency power source for the aircraft. Therefore, the battery should never be used for starting engines or servicing equipment if another source of power is available. Such unnecessary usage tends to shorten the life of the battery and keeps the battery in poor condition to meet emergency operation requirements. During the periods when the engines are idling or being started, the electrical loads should be kept at a minimum. The service life of the aircraft battery depends a great deal upon the frequency and quality of care it is given. Batteries that are abused or that receive careless treatment and servicing generally have their service life ended prematurely.

Since it is important to keep their weight at a minimum, aircraft batteries have a small capacity. Consequently, they must be used with great care.

Most aircraft batteries are equipped with a quick-disconnect unit as shown in figure 6-16 This unit is a heavy-duty connector with a handle attached to a threaded post. The battery cables can be disconnected from the battery post simply by turning the handle and pulling the quick-disconnect unit.

AT.59

Figure 6-16.–Typical aircraft lead-acid storage battery.

Aircraft batteries require a great deal more care than automobile batteries because of the unusual conditions under which they operate. The aircraft battery is usually shielded by enclosing it in a grounded, metal housing. (See fig. 6-16.) This completely shields the battery and the terminal connections. This shielding eliminates, to a large degree, radio-frequency interference from being induced into the communication system from the battery and its associated components.

Lead-Acid

The most common aircraft battery in use today is the lead-acid type. However, two recent types, which are known as the nickel-cadmium and the silver-zinc batteries, are being used in some aircraft.

Fundamentally, there is no difference in the operation of the lead-acid aircraft battery and the lead-acid automobile battery. Both types of batteries have their plates immersed in a solution of sulfuric acid and water and operate on the same basic principles. Batteries are covered in more detail in chapter 3 of Basic Electricity, NavPers 10086-B.

Nickel-Cadmium

Some nickel-cadmium batteries used in naval aircraft are physically and electrically interchangeable with the lead-acid type, while some are sealed units which use standard plug and receptacle connections which are used on

13290

other electrical components. These batteries generally require less maintenance throughout their service life.

The electrolyte used in nickel-cadmium batteries is a solution of potassium hydroxide. This solution is very caustic and will burn clothing, skin, etc.

The nickel-cadmium battery performs especially well at high discharge rates and at low temperatures.

Silver-Zinc

Silver-zinc batteries are used largely in military applications and in some industrial applications where their unique characteristics are sufficiently important to justify their comparatively high cost. These batteries are currently installed in various models of Navy helicopters.

The silver-zinc battery was developed for one major and one secondary purpose. The major purpose was to secure a large quantity of electrical power for both ground and emergency flight operations. The secondary purpose was to permit a design weight savings in new aircraft. A lightweight, silver-zinc battery provides as much electrical capacity as a much larger lead-acid or nickel-cadmium battery.

The battery's high electrical capacity per unit of space and weight is a result of the close plate spacing, the large degree to which the active plate materials are utilized, and the absence of heavy supporting grids in the plate. Silver-zinc batteries are capable of producing as much as six times more energy per unit of weight and volume than other types. Silver-zinc cells have been built with capacities ranging from tenths of ampere-hours to thousands of ampere-hours.

Silver-zinc batteries have a maximum service cycle life which is less than that of other types, but their life expectancy compares favorably with that of other types of batteries that are designed for maximum capacity per unit of space and weight such as nickel-cadmium.

AUXILIARY POWER UNITS

In this discussion the term auxiliary power unit is limited to those units which are portable, but are not installed aboard the aircraft. The units may be self-propelled, towable, or merely transportable; they may use diesel fuel, jet fuel, or gasoline. The generators may be driven by the unit's engine or it may have its own prime mover. Several types are discussed; however, before beginning a discussion of specific types of individual models, several generalizations should be mentioned.

When moving the APU into the vicinity of the aircraft, care should be taken to avoid collision with aircraft or other equipment. Flight lines and aircraft parking areas are normally crowded, and space between aircraft and equipment may not be sufficient to allow passage of the APU. Equipment and/or aircraft may have to be moved and repositioned to permit access to the aircraft to be serviced. When movement of the aircraft is necessary, the line crew should be notified, and requirements should be outlined. Local procedures and policies must be followed, and line safety regulations observed. Under NO conditions should the APU be used to move the aircraft, not even "a couple of feet."

Once access to the aircraft has been gained, the APU must be connected to the aircraft. Each unit has its own procedures for operation, but some general considerations apply to all. Prior to connecting the APU to the aircraft to be serviced, all aircraft power switches should be checked and placed in the proper position. (This requires familiarization with the aircraft; the information is available in the Flight Manual and in the Maintenance Instructions Manual for each model aircraft.)

Prior to making the actual connection, the cable and the receptacle should be inspected carefully for general condition and for correct polarity/phase. Many flights are aborted because external power cables have been inserted into aircraft with polarity or phase reversed due to careless insertion or defective cables.

The APU should not be connected to the aircraft with a "hot line"; the generator power switches should be off. After connection, the generator may be activated, and the switches turned on when stable operation is obtained.

During high load operation of APU's, the power cables frequently heat excessively and the cable voltage drop is quite noticeable. Nearly all of the mobile electric power plants (MEPP's) have an output current capability well in excess of the current rating of the cables. Therefore, when supplying power to large loads, the current ratings of the cables must be considered. If

13291

UNIT I - INTRODUCTION

Application of Drafting — Lesson 1

OBJECTIVE: To learn the importance of drafting and why we study it.

RELATED INFORMATION:

Drafting is the graphic language used in the industrial world by engineers and designers to express and record the ideas and information necessary for the building of machines and structures.

By using a logical system of related "views" known as an orthographic projection (see Fig. 1), intricate and complicated shapes may be clearly shown, exact sizes given, individual parts identified for assembly, and parts located in a machine in their correct functional position. (See Fig. 2)

FIG. 1

FIG. 2

the load requirements exceed the rating of the cable, the load should be reduced or a higher capacity APU should be obtained.

Mobile Electric Powerplants

NC-10 AND NC-10A.–The NC-10 and NC-10A powerplants are diesel engine-driven mobile powerplants, designed to supply 90 kva at 115/200 volts, 3-phase, 400 Hz for servicing, starting, and maintaining helicopters and jet aircraft. A portion of the generated electric power is rectified to supply 28 volts d.c. at 750 amperes (1,000 amperes intermittent) for aircraft starting.

The powerplant is enclosed in a steel housing, fabricated in two sections which are easily removed for servicing of the unit. Operating components are mounted on a four-wheel trailer, which is equipped with mechanical type internal expanding front wheel brakes. The brakes may be set by a hand lever or automatically set when the tow bar is in the vertical position.

Double hinged doors provide access to the control panel, starting components, and three output power cables.

The plant's electrical system is protected from overload by output circuit contactors, circuit breakers, over- and under-voltage relays, over- and under-frequency relays, thermal overload relays, and fuses.

The NC-10 powerplant was designed for use on carriers and shore stations. The NC-10A (fig. 6-17) was especially designed for Marine Corps shore duty activities. The operating features and technical data are the same for both plants, except that the NC-10A employs a self-propelled feature.

NC-12 AND NC-12A.–The NC-12 and NC-12A are diesel engine-driven powerplants, designed to supply 125 kva at 115/200 volts, 3-phase, 400 Hz for servicing, starting, and maintaining helicopters and jet aircraft. A portion of the generated electric power is rectified to supply 28 volts d.c. at 750 amperes (1,000 amperes intermittent) for aircraft starting. These units utilize dual power output circuits which make them capable of simultaneously delivering electric power for two P-3A aircraft.

The powerplants and components are mounted on a four-wheel trailer, equipped with mechanical front wheel brakes which are actuated by a hand lever or the spring-loaded tow bar. These units do not come equipped with self-propelled features; they must be towed.

The NC-12 AND NC-12A are similar except the NC-12 was designed for shore duty operation, while the NC-12A was designed for either carrier or shore-based use. The electrical characteristics are identical. Figure 6-18 depicts the NC-12A.

The technician will come in contact with many new types of powerplants such as the NC-10 series and NC-12 series, which will eventually replace the older plants such as the NC-5, NC-6, and NC-7 series.

AT.60

AT.61

Figure 6-18.–Mobile Electric Powerplant Type NC-12A.

13292

(NOTE: Most naval air stations and activities have training courses available to provide instruction in the use and operation of mobile powerplants, only licensed operators should operate this type equipment.

Table 6-1 shows a comparison of the major characteristics of the mobile electric powerplants discussed in the preceding paragraphs, as well as some older types still in common usage.

AIRBORNE AUXILIARY POWERPLANTS

Some of the larger aircraft are equipped with auxiliary powerplants installed at different locations on different aircraft. They are used to furnish electric power when engine-driven generators are not operating or when external power is not available. Aircraft auxiliary powerplants are particularly useful on seaplanes, which are often moored to buoys for long periods of time. Mooring lights must be on and communications equipment used while moored. The APP is utilized to furnish power since excessive battery usage must be avoided.

Another particular application for the powerplants is in large land-based aircraft. Here they are used to provide a constant voltage at a constant frequency. This is advantageous because the output of the APP is not dependent on aircraft engine rpm.

Some of these units use a gasoline engine to drive the generator, while others use a gas turbine. Figure 6-19(A) shows a gasoline engine-driven APP; figure 6-19(B) shows a gas turbine type.

Auxiliary powerplant logbooks must be kept on each powerplant. The operator of the powerplant is responsible for entering the operating time in the log each time the powerplant is used.

RECTIFIER UNITS

The use of a-c generators for primary electrical power in modern naval aircraft has been mentioned previously. One of the reasons for this is the saving in weight.

The size of wire required to deliver a given wattage can be considerably smaller, if the voltage is 115 volts a.c. rather than 27.7 volts d.c. Due to higher voltage and a four-wire (grounded neutral) system, the current carried in each wire is only a fraction of that required for the same power in a 28-volt d-c system. This permits the use of much smaller aircraft wiring with a great saving in weight. The a-c generator itself, especially in the larger sizes, is lighter than a d-c generator of comparable output. Many of the components for system control and protection are also lighter than comparable d-c components.

Even though the d-c generator is eliminated by the utilization of a.c. as a primary source of power, d-c voltages are required for proper functioning of many systems. This d-c voltage is obtained from a transformer-rectifier assembly.

Figure 6-20 is a schematic drawing of a transformer-rectifier unit. The transformer is a 3-phase, 400 Hz, stepdown type. The input is 115 volts a.c. to a delta connection, and the output is 22 volts a.c. across each leg of a wye connection. The rectifiers are of the selenium dry disk type, forming a bridge unit. After rectification (and minus the voltage drop across the rectifier), the output is 28 volts d.c. (Refer to chapter 16 of Basic Electricity, NavPers 10086-B for discussion of 3-phase power components.)

DECKEDGE POWER

The primary function of the deckedge electrical power system installed on aircraft carriers is to provide a readily accessible source of servicing and starting power to aircraft at almost all locations on the carrier's flight and hangar decks.

The 28-volt d.c. is supplied by motor-generators or rectified a.c. from remote a-c generators.

The 400 Hz, 3-phase a-c servicing voltage is usually supplied by these same a-c generators through stepdown transformers. Figure 6-21 shows a diagram of an electrical system which may be found on a modern carrier. The deckedge power may be supplied by service outlets at the edge of the flight deck or from recesses in the flight deck. All systems have standard remote control switches, service outlet boxes, and portable cables. Figure 6-22 shows a typical deckedge installation.

13295

Although there are some variations between carriers of different classes and aircraft of different models, this discussion and the associated figures represent a typical example. For explicit details concerning a specific installation, check the deckedge station and its power cables.

AT.64

Figure 6-20.—Transformer-rectifier.

The d-c service outlet box contains two male plugs. One is rectangular in shape and the other is oval. The rectangular plug provides servicing power and the oval plug provides starting power for aircraft with electrical starters.

The aircraft is equipped with an oval-shaped plug for applying d-c servicing power and a rectangular-shaped six-pin plug for applying 3-phase, 400 Hz, a-c servicing power. Power is applied to the aircraft by connecting the portable cables between the deckedge and aircraft plugs. To obtain d-c servicing power, the oval end of the portable cable is connected to the oval plug in the aircraft and the opposite (rectangular) end is connected to the rectangular deckedge plug.

To obtain 3-phase, 400 Hz, a-c service power, the portable a-c plug is connected to the aircraft and the opposite end to deckedge a-c service power box. The ends of the a-c portable cable are interchangeable.

Figure 6-23 illustrates how these connections may be made. To obtain d-c servicing

AT.65

AT.67

Figure 6-23.–D-c and a-c power cables and plugs.

power to the aircraft, connect the cable from A to A'; to obtain a-c service power connect it from B to B'.

The a-c service power is usually provided at the same station as the d-c power. The cable is usually permanently attached to the service outlet box. Although its plug is rectangular, there is no danger of connecting it to the d-c service power receptacle as the size and number of pins are not the same.

Care should be exercised when connecting auxiliary power cables to the aircraft. The cables are heavy, and damage to the aircraft may result if there is not sufficient slack in the cables.

GROUND COOLING SYSTEMS

The purpose and need for ground cooling will vary with type of aircraft and climatic conditions. When repairing high-voltage equipment aboard large aircraft in a tropic zone, ground cooling of the aircraft cabin reduces the hazard of shock due to clothing being wet with perspiration. It may also prevent shorting of components by falling perspiration.

An additional reason for using ground cooling equipment, even in temperate zones, is the fact that electronic equipment produces large quantities of heat. This heat must be dissipated or the equipment would achieve temperatures that could cause damage and create a fire hazard.

The combination of tropic heat and equipment heat in an aircraft without a cooling system operating often creates a hazard of heat-stroke or heat exhaustion. When the aircraft is airborne, various means are used to accomplish the required cooling. Some electronic equipments have fans built in for cooling. Others generate so much heat that a blast of air from outside the aircraft must be used. Some large magnetrons are liquid cooled–the liquid, in turn, is cooled by air directed over a radiator.

When a large quantity of air is required for cooling, a common source for the air is the aircraft's ventilation system. However, line maintenance, ground operational checks, and functional checks are usually performed without the aircraft's ventilation system operating, since this system is driven by the aircraft engines. Therefore, a substitute air supply must be provided for the air distribution system.

The air distribution system illustrated in figure 6-24 consists of two subsystems. One subsystem controls and distributes the incoming fresh air supply; the other controls exhaust airflow through electronic racks and tactical crew station cabinets to the atmosphere. The fresh air distribution subsystem is designed to use fresh, temperature-controlled air from two engine-driven cabin air compressors. An alternate source of unconditioned fresh air, called the auxiliary ventilation system, may be used in flight to supplement the temperature-controlled air from the cabin air compressors.

The auxiliary ventilation system receives air from a ram air inlet. This inlet and a ground air connection are adjacent to one another in the nosewheel well and connect to a

13297

Figure 6-24.–Air distribution system of an aircraft. (A) Inlet air system; (B) exhaust air system. AT.68

13298

common duct. This duct connects to the duct which normally carries air from the cabin air cycle cooling system to the cabin air riser (vertical duct). The air from either of these alternate fresh air sources is routed the same as air coming from the cabin air cycle cooling system. Therefore, the ground connection permits the output from a mobile air conditioner to be routed through the duct which normally carries air from the cabin air cycle cooling system. This is particularly desirable for line maintenance purposes.

ACM-2905-F22

The ACM-2905-F22 is a mobile aircraft air conditioner that is capable of delivering 21.9 tons of refrigeration at 2,500 cfm (cubic feet per minute). A ton of refrigeration is the amount of cooling resulting from the absorption of enough heat to melt a ton of ice at 32° F in a 24-hour period. This is equivalent to a cooling capacity of approximately 12,000 Btu per hour.

The air conditioning unit consists of a 7-cylinder, 40-ton radial compressor directly connected to a 150-hp internal combustion engine; large cooling coils; and an evaporative condenser. (See fig. 6-25.) The engine uses conventional automotive type electrical starting and battery charging equipment.

The unit is housed in a 12-foot truck body and is controlled from a simple panel located on the outisde of the truck for ease of operation. (See fig. 6-26.)

A built-in safety system cuts off the ignition to the air-conditioning unit whenever the following conditions occur:

1. Loss of engine oil pressure.
2. Engine water termperature too high.
3. Compressor suction pressure too low.
4. Compressor discharge pressure too high.

Should any of these conditions occur, an alarm bell will sound, a red light on the control panel will be illuminated, and the engine will automatically shut down.

The control panel, mounted in the left side of the unit, contains the following instruments and controls:

1. Panel lights and switch. Two panel lights are supplied to provide illumination for the control panel.
2. Interior light switch and pilot light. This switch is provided to operate lights situated at other points in the installation. The green pilot light indicates when the interior lights are on.
3. Safety release switch. This is a push-button switch which is used to remove the safety controls from the circuit. Should a shutdown occur due to excessively high water temperature, it might be necessary to hold this button in while starting the engine after the cause of the shutdown has been corrected.
4. Key ignition switch. This switch prevents unauthorized persons from attempting to operate the machine. When the switch is turned off, the entire electrical system is disconnected and the starting motor cannot be operated.
5. Tachometer. The electric tachometer indicates the engine speed in revolutions per minute.
6. The ammeter. The ammeter indicates the rate of charge or flow of electric current being supplied to the battery by the generator, or the rate of discharge from the battery.
7. Oil pressure gage. The oil pressure gage indicates the pressure of the engine oil, not the amount of oil in the crankcase.
8. Water temperature gage. The temperature gage indicates the temperature of the cooling system of the engine (not the air conditioner).
9. Starting button. Pressing the button, after the key switch is turned on, completes the circuit between the battery and starting motor to crank the engine.
10. Choke control. Pulling the choke out supplies a richer mixture for starting when the engine is cold.
11. Vernier type throttle control. The throttle is equipped with a locking device to hold the control in any desired position.
12. Fuel tank gage. The fuel gage is electrically operated and is connected to the fuel tank sensing unit. The gage indicates the level of gasoline in the tank and will only register after the ignition switch is turned on.
13. Evaporator-condenser water tank gage. Operating similarly to the above, this gage in-

13299

AT.70

Figure 6-25.—Air-conditioning unit, functional diagram.

dicates the water level in the evaporative condenser supply tank.

14. Winter switch. This switch is used to operate a solenoid valve in the refrigerant line. In winter, when it is desired to operate the engine without refrigeration, the switch is to be set at the OFF position. For normal operation, however, the switch is to be left ON.

15. Refrigeration gages. These three instruments (reading from left to right when facing the control panel) are: Compressor suction pressure gage, compressor oil pressure gage, and compressor discharge pressure gage.

KOKA 567A

This unit, described as "air conditioner, portable electric," is basically an electric-driven air-conditioning unit mounted on a four-wheel trailer. The unit is intended for use on the flight line to supply cooling air to aircraft during electronic testing or other operational testing.

With a refrigerating capacity of 31.2 tons, the unit uses an 8-cylinder compressor driven by a 60-hp, 440-volt, 3-phase, 60-hertz motor to deliver a maximum of 3,500 cfm of air at a minimum temperature of 45° F. This airflow may be varied by means of a manual damper located in the supply air outlet. Adjustment to requirements can be made by the operator and airflow readings of pressure and volume can be read directly at the instrument panel. An automatic temperature control device will maintain the leaving-air temperature (at the setting of a thermostat with a range of 0° to 120° F, located on the control panel) by varying the volume damper to control airflow. This feature permits maintaining constant air temperature with a slight variation of supply airflow.

13301
13300

AT.71

Figure 6-26.–Air-conditioning truck mounting and control panel.

The refrigeration unit is automatically prevented from operating when the outside ambient air temperature is less than 40° F.

NR-3

The NR-3 is a trailer-mounted, Freon cycle, 120-hp, engine-driven mobile air-conditioning unit. (See fig. 6-27.) This unit is completely selfsustaining and carries enough fuel and water to provide 4 hours of continuous operation. A lunette eye, with a shock control device, is attached to the end of a steerable tow bar and will allow the air conditioner to be towed up to speeds of 40 mph on paved surfaces. A tow bar retainer allows the tow bar to be stowed in the vertical position when not in use. A parking brake provides a means of securing the fully loaded unit on grades up to 35 percent.

This air-conditioning unit supplies cool, moisture-free air to the cabin conditioning and cooling equipment systems during ground checkout and testing of an aircraft's various systems. The unit is capable of delivering 294,000 Btu (24.5 tons gross) of conditioned air. This produces 100 pounds of airflow, at a pressure of 3 pounds per square inch, throughout a range in ambient temperatures from 10° C (50° F) to 43° C (133° F) when measured at sea level. The equipment is designed to operate at altitudes up to 5,000 feet above sea level.

SERVICING UNIT CP 105

The AiResearch CP 105 is a gas turbine-driven power and refrigeration aircraft ground support unit furnished to the Navy in three different configurations. It is used primarily in support of the RA-5C and F-4B aircraft. All three arrangements employ basically the same system, using a small gas turbine to supply electric power and air for refrigeration, main aircraft engine starting, and pilot suit pressurization.

13301

If this were not done, chaos and disorder would result from the lack of a standardized method of conveying a message or idea through means of drawings.

To be able to write this graphic language easily and accurately, the aid of drawing instruments is required. When these implements are used, the drawing is called an instrument drawing. When done without the assistance of instruments, it is known as freehand drawing. Training in both of these methods is necessary for the draftsman.

Our basic objective then, is to study this language so that we may write it, express ourselves clearly to one familiar with it, and be able to read it readily when written by another.

QUESTIONS: In answering the questions, use the drawing of the block shown above.

1. Give the overall (length, width, height) dimensions of the block.

2. What does the dotted line mean?

3. In your opinion, why is drafting important?

4. List some applications of the drafting trade.

5. Why are dimensions placed on the drawing?

AT.72

Figure 6-27.–NR-3 air conditioner.

(NOTE: Electric power is generated by an air-driven turbine.)

The RCPP 105 (one of the three available models) is mounted in a 22-foot long aerodynamic pod for air transportation as an aircraft external store. On the RA-5C, the pod is transported under the wing; on the F-4B, it is carried under the fuselage. A cradle type towable trailer is provided for ground movement of the unit. (See fig. 6-28.)

The RCPT 105 is mounted on a self-propelled, low-silhouette (38 inches from the ground) trailer.

The tractor unit is similar to the RCPT 105 except that the turbine-driven unit is mounted on a diesel tractor.

SUCCI 13303

CHAPTER 7

HANDTOOLS

A skilled technician can be identified by the way he handles and cares for his tools and materials. Tools are a costly investment and should be cared for and used to full advantage. There seems to be something about a good tool that helps the average technician turn out better than average work. This fact alone more than justifies the slightly higher cost of quality tools. Even more important is the fact that low quality tools become defective more readily and can result in injury to the user or damage to the equipment undergoing repair.

In the same manner, proper use of quality materials improves the quality of any maintenance task and reduces the possibility of new failures. The primary duties of all maintenance personnel are to become thoroughly familiar with the tools and materials of his trade and be proficient in their care and use.

HANDTOOLS

For purposes of this discussion, the term "handtools" will be used to refer to the small portable or fixed power tools commonly available in electronics maintenance shops or used by electronics maintenance personnel during work on aircraft, as well as those normally classified as nonpowered handtools.

SAFETY, USE, AND CARE OF HANDTOOLS

Carelessness is the greatest menace in any shop. It must come from the man himself; the machine alone cannot inflict injury. Lack of care is the cause of most accidents in electrical and electronics shops today. It should be remembered that all power tools are potentially dangerous. It is unsafe to lean against any that is in motion, or that may be started in motion by anyone else. Treat a machine with businesslike respect and there is no need to fear it. Do not start a machine until its operation has been fully explained by a competent instructor.

Chapter 3 of this manual contains some information concerning safety precautions and practices involving machinery and tools; that material should be reviewed frequently. Other excellent sources of information regarding handtools and their use and care are the Rate Training Manuals Airman, NavPers 10307-B, and Basic Handtools, NavPers 10085-A. Since these manuals are basic to all aviation ratings, the material covered in them is not duplicated in this discussion; review of that material should be accomplished before proceeding with this manual.

The following two basic safety precautions may be used to summarize this idea, and they cannot be emphasized too strongly:

1. Use the proper tool for its own specific function, and use it in the proper manner.
2. Maintain all tools in proper working order and in a safe condition. Sharpen or replace dulled cutting tools, replace broken or defective tools, and protect tools from damage while in use or in storage.

When performing any function requiring the use of tools and/or materials, arrange them so that they are easily accessible but are not in a position to interfere with the work. This arrangement increases efficiency as well as safety.

Tools should be cleaned and inspected after the job has been completed. Return all tools to their proper storage place. If a tool becomes worn, damaged, or broken, report it to the senior member of the shop so that proper steps may be taken for replacement or repair.

13304

GENERAL TOOLS

Although the previously mentioned basic courses provide many details regarding the common general tools, a few additional comments are of importance to the avionics maintenance technician.

Never use a center punch on extremely hard metals or to remove bolts by force; to do so will dull the point. Never use a pin punch as a starting punch–a hard blow may cause the slim shank to break. Always use the largest starting and pin punches that will fit the hole. When using punches, do not strike a glancing blow; the punch may break, and broken pin punches are difficult to remove.

Do not hammer on a screwdriver. If an obstruction is in the slot, apply a driving force with the heel of the hand or remove the obstruction with a file. Never use a screwdriver as a pry bar, lever, or chisel. Do not use pliers or wrenches on a screwdriver to increase torque.

When using a grinding wheel, insure that the guard is in place. If it is necessary to use the wheel with the guard removed, stand to one side to avoid flying particles of emery or metal. Use safety goggles when grinding screwdriver blades or other metal objects. Nonferrous metals should never be ground with ordinary grinding wheels due to the danger of the wheel becoming loaded with the material and possibly exploding. Use the rest stand when possible, but insure that the rest is close to the grinding wheel.

When drilling, never use the hand to hold the work being drilled. Use a vise or a clamp. The same idea applies to work being soldered, filed, or sawed.

Know Your Screwdrivers

Using a Reed and Prince screwdriver for working on Phillips screws (or vice versa) can result in a ruined tool or a ruined screwhead, making it difficult to remove the screw. Because of the difference in design of the two screws, the screwdrivers should not be used interchangeably. In general, Reed and Prince screws are used for airframe structural applications, while Phillips screws are found most often in component assemblies.

Figure 7-1 shows the differences between types. The Phillips screwdriver has about 30-degree flukes and a blunt end, while the Reed and Prince has 45-degree flukes and a sharper, pointed end. The Phillips screw has beveled walls between the slots; the Reed and Prince, straight, pointed walls. In addition, the Phillips screw is not as deep as the Reed and Prince.

Ways to identify the right screwdriver are as follows:

1. If it tends to stand up unassisted when the point is put in the head of a vertical screw, it is probably the proper one.
2. The outline of the end of a Reed and Prince screwdriver is approximately a right angle, as seen in the illustration.
3. Know the descriptions of both types. Using the right tool saves time and trouble, and is good maintenance practice.

Soldering Iron

All high quality irons operate in the temperature range of 500° to 600° F. Even the little 25-watt midget irons produce this temperature. The important difference in iron sizes is not temperature, but thermal inertia (the capacity of the iron to generate and maintain a satisfactory soldering temperature while giving up heat to the joint to be soldered).

AE.35

Figure 7-1.–Matching cross-slot screws and drivers.

13305

AE.46

Figure 7-2.–Resistance soldering unit.

AE.44

Figure 7-3.–Pencil iron kit with special tips.

adjusted for as long as 3 seconds soldering time. This set is especially useful for soldering cables to MS/AN plugs and similar connectors–even the smallest types available.

In use, the double-tip probes of the soldering unit are adjusted to straddle the connector cup to be soldered. One pulse of current heats it for tinning and, after the wire is inserted, a second pulse of current completes the job. Since the soldering tips are hot only during the brief period of actual soldering, burning of wire insulation and melting of connector inserts are greatly minimized.

The greatest difficulty with this device is keeping the probe tips free of rosin and corrosion. A cleaning block is mounted on the transformer case for this purpose. Some technicians prefer fine sandpaper for cleaning the double tips.

CAUTION: Do not use steel wool. It is dangerous when used around electronic equipment.

Pencil Iron and Special Tips

An almost indispensable item is the pencil type soldering iron with an assortment of tips (fig. 7-3). Miniature soldering irons, with wattage ratings of less than 40 watts are easy to use and are recommended. In an emergency, larger irons can be converted and used on subminiature equipment as described later in this section.

One type of iron is equipped with several different tips that range from one-fourth to one-half inch in size (diameter) and are of various shapes. This feature makes it adaptable to a variety of jobs. Unlike most tips which are held in place by setscrews, these tips have threads and screw into the barrel. This feature provides excellent contact with the heating element, thus improving heat transfer efficiency. A pad of "antiseize" compound is supplied with each iron. This compound is applied to the threads each time a tip is installed in the iron, thereby enabling the tip to be easily removed when another is to be inserted.

A special feature of this iron is the soldering pot that screws in like a tip and holds about a thimbleful of solder. It is useful for tinning the ends of large numbers of wires.

The interchangeable tips are of various sizes and shapes for specific applications.

13307

Extra tips may be obtained and shaped to serve special purposes. The thread-in units are useful in soldering subminiature items. The desoldering units are specifically designed for performing special and individual functions.

Another advantage of the pencil soldering iron is its possible use as an improvised light source for inspections. Simply remove the soldering tip and insert a 120-volt, 6-watt, type 6S6, candelabra screwbase lamp bulb into the socket.

If leads, tabs, or small wires are bent against a board or terminal, slotted tips may be used to simultaneously melt the solder and straighten the leads.

A hollow tip, which fits over a pin terminal, may be used to desolder and resolder wiring at cables or feed-through terminals.

Many microminiature components have multiple connections, all of which must be desoldered to permit removal of the component in one operation. These connections may be desoldered individually by heating each connection and brushing away the solder. With this method, particular care must be taken to insure that loose solder does not stick to other parts or become lodged where it may cause a short circuit. A more efficient method is to use the specially shaped desoldering units (fig. 7-3). Select the proper size and shape tip that will contact all terminals to be desoldered—and nothing else. Do not permit the tip to remain in contact with the terminals too long at one time.

If no suitable tip is available for a particular operation, an improvised tip may be made. Wrap a length of copper wire around one of the regular tips and bend the wire into the proper shape for the purpose. Insure that the improvised tip contacts all connections and nothing else. This method also serves to reduce tip heat when a larger iron must be used on miniature components. (See fig. 7-4.)

In connection with the discussion of soldering tools and devices, the selection of solder and flux is also critical. A small diameter rosin core solder with a high tin-lead ratio is normally preferred (63/37 or 60/40). Normally the higher the lead content, the higher the melting point. In miniature circuits heat is critical, and the higher tin-to-lead ratio requires less heat to make a strong and lasting joint. An exception is in soldering a silver plated or solid silver item. For this application the solder must contain 2 to 3 percent silver to prevent chemical action which could destroy the component.

AT.74

Figure 7-4.—Improvised tip to reduce heat.

Any flux used must be noncorrosive and nonconductive, to prevent corrosion, shorts, and electrical leakage.

Soldering Aids

Several devices other than the soldering iron and its tips are required in soldering miniature circuits.

Some type of thermal shunt is essential in all soldering operations which involve heat-sensitive components. Pliers, tweezers, or hemostats may be used for some applications, but their effectiveness is limited. A superior heat shunt is shown in figure 7-5. Proper use of the heat shunt permits soldering the leads of component parts without overheating the part itself.

For maximum effectiveness, any protective coating should be removed before applying the heat shunt. The shunt should be attached carefully to prevent damage to the leads, terminals, or component parts. The shunt should be clipped to the lead, between the joint and the part being protected. As the joint is heated, the shunt absorbs the excess heat before it can reach the part and cause damage.

13308

A small piece of beeswax may be placed between the protected unit and the heat shunt. When the beeswax begins to melt, the temperature limit has been reached. The heat source should be removed immediately, but the shunt should be left in place.

Premature removal of the heat shunt permits the unrestricted flow of heat from the melted solder into the component. The shunt should be allowed to remain in place until it cools to room temperature. A clip-on type shunt is preferred because it requires positive action to remove the shunt, but does not require that the technician maintain pressure to hold it in place.

Another invaluable soldering aid is the "solder sucker" syringe. One type is shown in figure 7-6. Its purpose is to "suck up" excess solder (and incidentally the excess heat) from a joint. The only requirements of an efficient solder sucker are a controllable source of vacuum (squeeze bulb), a solder receiver, and a tip. The tip must be able to withstand the heat of molten solder. Teflon is ideal, but is difficult to acquire through Navy supply channels. A silicon rubber-covered Fiberglas sleeving with an inner diameter of 0.162 inches (FSN 9N5970-285-0488) and the bulb from a medicine dropper makes a suitable syringe. (The glass or plastic tip of the medicine dropper cannot withstand the heat.)

SOLDER

Two types of solder are available—the tin-lead alloy known as soft solder and the so-called hard or silver solder. Soft solder alloys permit the use of lower soldering temperatures and are therefore recommended for electronic applications. Where a joint of greater strength is required, silver solder is employed.

Most solder alloys do not liquefy immediately as the temperature is increased. Ordinarily they change from the solid state to a plastic semiliquid, and finally become completely liquid. Most tin-lead solders enter the plastic state at 358° F and become wholly liquid at various temperatures, dependent upon the individual composition. A combination of 63 percent tin and 37 percent lead has the lowest melting point (361° F) for the tin-lead group. However, since it changes from solid to liquid without an intervening plastic state, it is susceptible to fracture from slight vibration while cooling.

(Solder is commonly referred to as 70/30, 60/40, etc. This is the tin-lead content.)

FLUXES

All common metals are covered with a nonmetallic film, usually an oxide of the material, which prevents them from making the intimate contact so necessary for a good electrical connection. The purpose of a flux is to remove the oxide from the surfaces to be soldered, not to clean them. Flux cannot replace good cleaning methods in preparing surfaces for soldering. Without a clean, inti-

AE.47

Figure 7-5.–Heat shunt.

AT.75

Figure 7-6.–Solder sucker.

13309

mate contact, poor soldering techniques may result in a mechanically weak, high resistance joint—a so-called rosin joint in the case of rosin-base flux.

Solder fluxes may be divided into three general groups—rosin, organic, and chloride (sometimes called acid). The residue from the rosin-base fluxes is noncorrosive and electrically nonconductive, making them highly acceptable for use in military electronic equipment. The organic and chloride types are seldom used (sometimes even prohibited) because of their corrosiveness. Actually, only rosin-base flux is recommended for electronic applications.

ROSIN flux is actually very active when melted by heat. However, after the normal heat of the soldering operation is removed, the dry solid residue is noncorrosive and electrically nonconductive. Activated or intensified rosin-alcohol fluxes are permitted by MIL-S-6872 if they are noncorrosive. (For details, consult this specification.)

ORGANIC fluxes consist of mild organic acids and bases. These fluxes are almost as active as the organic salts, but their period of activity is brief due to their susceptibility to thermal decomposition. This limits corrosion and therefore may be used in applications where the soldered assembly lends itself to residue removal.

CHLORIDE type fluxes are not recommended for electronic applications.

SPECIAL TOOLS

A wide variety of special tools is required to maintain the modern aircraft of today's Navy. These tools are furnished by the manufacturers of the aircraft, engines, and related equipment.

Proper use of special tools greatly reduces the man-hours required for maintenance work.

These tools are listed in allowance lists published by the Naval Air Systems Command, and their use is explained in the Maintenance Instructions Manual or the Service Instruction Manual covering the particular aircraft, engine, or piece of equipment for which they were designed. An example of a special tool that is required for special maintenance of equipment, is the cable assembly connector wrench. This wrench is used to remove the sonar dome from the electrical special purpose cable assembly. (See fig. 7-7.)

NONMAGNETIC TOOLS

Tools made of nonmagnetic materials are available through normal supply channels. They are used for performing specific maintenance functions on certain classes of equipment or components—such as maintaining the detecting heads of MAD equipment. These tools, normally made of beryllium-copper, are used because steel tools may become magnetized through normal use.

Restricting the use of the nonmagnetic tools to the purpose for which they are intended will increase their value to the technician. Use of these tools for general maintenance would allow them to transfer metal or other foreign particles into electronic equipment. The gears and bearings of the detecting head are easily fouled by small particles of dust or metal. In addition to mechanical fouling, the introduction of metal particles that are magnetized would cause magnetic noise in the detecting head.

Nonmagnetic tools should also be used in tuning RF circuits which are susceptible to frequency change resulting from the introduction of new magnetic fields (or the distortion of the existing magnetic fields). Many slug-tuned IF circuits involve this potential trouble.

Good general maintenance practice involves wiping the tools before use and again after use. This is especially advisable in the case of nonmagnetic tools. A lint-free cloth dampened with a suitable cleaning solvent may be used for this purpose.

AT.76

Figure 7-7.—Cable assembly connector wrench.

AIR 13310

Nonmagnetic metals are usually softer than steel, so use of these tools for general maintenance could also damage the tools.

INSULATED TOOLS

Safety considerations require use of insulated tools whenever the danger of electrical shock or short circuit exists. Many types of tools are available in insulated form directly through supply channels at little or no additional cost. These tools should be obtained and used whenever available. However, many types of insulated tools are not readily available (or are available only at considerable added expense). If essential, these tools should be procured or conventional tools may be modified. Insulated sleeving may be put on the handles of pliers and wrenches and on the shanks of screwdrivers. Tools modified in this manner should be used only for low voltage circuits because of the limitations of the insulating materials. For higher voltage uses, special insulating handles are available for many of the common types of tools.

In some instances, it is necessary to use tools which are made of insulating material, rather than merely having an insulating handle. In these instances, the tools should be requisitioned through normal supply channels, if possible. If they are not available through normal supply channels, they may be purchased on the open market.

TORQUE WRENCHES

There are times when, for engineering reasons, a definite pressure must be applied to a nut. In such cases a torque wrench must be used. The torque wrench is a precision tool consisting of a torque-indicating unit and appropriate adapter or attachments. It is used to measure the amount of turning or twisting force applied to a nut, bolt, or screw.

The three most commonly used torque wrenches are the deflecting beam, dial indicating, and micrometer setting types (fig. 7-8.) When using the Deflecting Beam and the Dial Indicating torque wrenches, the torque is read visually on a dial or scale mounted on the handle of the wrench.

To use the micrometer setting type, unlock the grip and adjust the handle to the desired setting on the micrometer type scale, then relock the grip. Install the required socket or adapter to the square drive of the handle. Place the wrench assembly on the nut or bolt and pull in the desired direction with a smooth, steady motion. (A fast or jerky motion will result in an improperly torqued unit.) When the torque applied reaches the torque value which is indicated on the handle setting, the handle will automatically release or "break" and move freely for a short distance. The release and free travel is easily felt, so there is no doubt the torquing process is complete.

To assure getting the correct amount of torque on the fasteners, all torque handles must be tested at least once a month or more often if usage indicates it is necessary.

The following precautions should be observed when using torque wrenches:

1. Do not use the torque wrench as a hammer.
2. When using the micrometer setting type, do not move the setting handle below the lowest torque setting. However, it should be placed at its lowest setting prior to returning to storage.
3. Do not use the torque wrench to apply greater amounts of torque than its rated capacity.
4. Do not use the torque wrench to break loose bolts which have been previously tightened.
5. Never store a torque wrench in a toolbox or in an area where it may be damaged.

Torque Information

The torque table (table 7-1) may be used as a guide in tightening nuts, bolts, and screws whenever specific torque values are not called out in maintenance procedures. Using the proper torque allows the structure to develop its designed strength and greatly reduces the possibility of failure due to fatigue.

Threads must be free from grease or oil. Lubrication changes the torque value and will result in overtorquing.

When castellated nuts are used, they should be tightened to the lower torque limit; then continue tightening until cotter pin hole is

013313 11

UNIT I - INTRODUCTION

How to Sharpen a Drawing Pencil — Lesson 2

OBJECTIVE: To learn the art of sharpening a drawing pencil.

RELATED INFORMATION:

In order for one to draw sharp, clear lines - which is imperative in drafting - he must learn to sharpen a drawing pencil properly. First, cut away the wood from the unlettered end with a penknife to make a long point, as shown at A, and then sharpen the lead by turning or twirling the pencil against the sandpaper pad. The result should be a conical point as shown at B. Naturally, it will take experience and practice to achieve best results.

Some draftsmen prefer a flat or wedge point (see C). For this type of point, the draftsman in sharpening the pencil should attempt to flatten the lead on the sandpaper pad. This is merely another method of sharpening a drawing pencil which certain individuals prefer. The end result, however, should be the same - sharp, clear lines.

Today, many draftsmen use mechanical drawing pencils. Here a long lead is inserted in the pencil and sharpened as above. There are also modern mechanical sharpening devices issued by several manufacturers of drafting equipment.

QUESTIONS:

1. Why use so much time in sharpening a drawing pencil?
2. Why must a draftsman use sharp, clear lines?
3. Explain the care and use of a mechanical drawing pencil.
4. Why must a draftsman be neat?

AT.77

Figure 7-8.–Torque wrenches.

alined with slots in nut. Do not back off nut to aline hole.

When it is necessary to tighten from the bolthead, use the high side of the torque range. If necessary, the maximum allowable tightening torque may be used.

When corrosion-resistant steel bolts are used, they should be lubricated with an anti-seize compound. Corrosion-resistant steel bolts and nuts must be used together. Use shear nut torque values when tightening these bolts.

RELAY TOOLS

Two of the more common handtools used to repair relays are the burnishing tool and the point bender. The use of these two items is discussed in the following paragraphs.

Burnishing Tool

Many relays have been damaged or ruined by the use of sandpaper or emery cloth to clean the contact points. Use of these abrasives causes bending of the contacts; and attempts to straighten them with long nosed pliers cause further damage, eventually requiring replacement of the relays. This can be avoided by using a burnishing tool to clean dirty contact points.

Figure 7-9 illustrates a burnishing tool being used on a relay.

Two common types of burnishing tools are stocked in supply activities and may be obtained through normal supply channels. These two common burnishing tools are 2 33/64 inches and 5 inches in length.

Be sure to clean the tool thoroughly with alcohol and do not touch the tool surface with your fingers prior to use.

Burned and pitted contacts cannot be repaired by burnishing. Relays having trouble this serious should be replaced.

Point Bender

Another handy tool that is often found in a toolbox is a point bender. The point bender (fig. 7-10) is used to straighten bent relay contacts. This bender can be fabricated locally from 0.125-inch diameter rod stock according to the dimensions in the figure.

13312

Table 7-1.—Torque values in inch-pounds.

Wrench size (in.)	Standard nuts, bolts, and screws		
	Bolt, stud, or screw size	Tension type nuts AN310 and AN365	Shear type nuts AN320 and AN364

NOTE: To convert to foot-pounds, divide inch-pounds by 12

WIRE AND CABLE TOOLS

An innovation in electrical connectors is the taper pin electrical connector for aircraft. The taper pin works on the principle of driving a taper wedge into a tapered hole and depending on friction to retain the pin in the hole. The taper pin connector makes a very good electrical and mechanical connection because of the high metal to metal contact pressure developed during the driving action of the insertion tool. Taper pins permit circuit changes to be quickly and easily performed without a soldering iron. Tests show that vibration and corrosion, over a period of time, improve the electrical continuity and increase the mechanical pulling force required to remove a taper pin. Another advantage of taper pins is the accessibility of test points for voltage and circuit continuity checks.

Insertion and Removal

A special tool, shown in figure 7-11, is used to properly insert the taper pin into the terminal block socket. The insertion tool has a calibrated

13313

AT.78

Figure 7-9.–Burnishing tool.

driving spring, a calibrated pull test spring, a taper pin captive key, and a taper pin removal feature.

The driving spring adjusts to apply the proper driving impact to the pin. The pull test spring adjusts to apply the correct pull force on the pin to check for proper pin insertion. The captive key insures that each taper pin has a 100 percent pull test before the tool is disengaged from the pin. The removal lever is rotated to remove the taper pin from the terminal block socket.

In order to maintain the reliability of the system, it is imperative that the taper pin be properly inserted into the terminal block sockets. Pushing the pins into the sockets with the fingers or pliers will not make them stay–they must be driven in with the insertion tool. The tool must be calibrated to insure that the proper pressures are used. When inserting the taper pins, the insertion tool must be held at right angles to the terminal block, and pushed straight toward the terminal block without twisting the tool. The pins are very sensitive to twists, which could cause a faulty connection or a broken pin. Bent or broken pins should always be replaced. However, if correct installation procedures are followed, a taper pin may be installed and removed as many as 25 times before a replacement is necessary. A properly installed taper pin will pass the pull test of the insertion tool.

Three different sizes of taper pins are used to terminate wires from size 16 through size 22. The sizes are identified by color coding of the insulating sleeves. A crimping tool is used to attach the taper pin to the wire. This taper pin crimping tool is similar to other types of wire terminal crimping tools, such as those discussed later in this chapter.

Stripper

Nearly all wire and cable used as electrical conductors are covered with some type of insulation. In order to make electrical

AT.79

Figure 7-10.–Point bender.

13314

AE.36

Figure 7-11.–Taper pin insertion and removal tool.

connections with the wire, a part of this insulation must be removed, leaving the end of the wire bare. To facilitate the removal of this insulation, use a wire and cable stripping tool similar to the one shown in figure 7-12.

Although several variations of this basic tool are available, the most efficient and effective is the type illustrated. Its operation is extremely simple–insert the end of the wire in the proper direction to the depth to be stripped, position the wire so that it rests in the proper groove for that size wire, and squeeze. The tool functions in three steps as follows:

1. The cable gripping jaws close, clamping the insulated wire firmly in place. The wire must be inserted so that the jaws clamp the main section of the wire rather than the end to be stripped.

2. The insulation cutting jaws close, cutting the insulation. If the wire is not inserted in a groove, the conductor will also be cut. If the wire is positioned into too small a groove, some of the strands will be severed. If the groove is too large, the insulation will not be completely severed. Inserted properly into the correct groove, the insulation will be cut neatly and completely, and the wire will not be damaged.

3. The two sets of jaws separate, removing the clipped insulation from the end of the wire.

If cable and wire strippers of this type are not available, notches may be cut in the jaws of diagonal pliers or pocket fingernail clippers, using jeweler's files. Care must be taken to file the grooves into the proper positions in opposing jaws, and the size of the groove must be appropriate for the size wire on which it is to be used. When properly modified, these tools will perform satisfactorily if the more desirable stripper is not available.

16315

AE.37

Figure 7-12.–Wire and cable stripper.

CRIMPING TOOLS

Type MS 25037-1

The standard tool MS 25037-1, issued for crimping solderless terminals, is for use with standard insulated copper terminal lugs manufactured according to MS 25036. The standard tool employs a double jaw to hold the terminal lug or splice. One side of the jaw applies crimping action to fasten the terminal to the bare wire when the terminal is inserted, as shown at the left in figure 7-13. When the tool is used correctly, a deep crimp is placed in the B area of terminal lugs and splices, as shown in diagrams on the right of the figure. A shallow crimp is applied to the portion of the terminal or splice which extends over the insulation of the wire, as indicated by the A area in the diagrams. This clamping action is provided by a recessed portion in the other side of the divided jaw. A guard, which should be in the position shown when crimping terminals, aids in proper positioning of the terminal. However, the guard must be moved out of the way when the tool is used for crimping splices.

Without the guard, the tool may be used incorrectly; for example, the terminal might be inserted from the wrong side of the tool. The result is that the deep crimp is placed in the A area of the terminal or splice and, although the wire may be held securely in place, the connection is poor. Common sense indicates that the deep crimp must clamp the metal of the terminal to the bare metal of the wire in order to provide a good electrical and mechanical connection.

The MS 25037-1 tool requires occasional checking. A No. 36 (0.106) drill rod should not be able to enter the smaller (red or blue) nest when the tool is fully closed. If it does enter, have the tool repaired.

Instruction in proper crimping procedure should be furnished to all who need to make solderless terminal connections. Handbook of Installation Practices for Aircraft Electric and Electronic Wiring, NavAer 01-1A-505, contains detailed procedures for using many solderless connector tools.

Type MS 3191-3

This tool is the latest standard crimping tool designed specifically for use with type MS 3191 contacts for electrical connectors.

13316

AE.38

Figure 7-13.–Crimping tool MS 25037-1.

It features interchangeable heads to accommodate various size terminals. It may be used with the turret (fig. 7-14 (A)) for normal use, or without the turret (fig. 7-14 (B)) for eyeball crimping.

Before using the tool, the correct selection must be made on the positioner head and also on the indentor gap selector plate. To release the turret for indexing, press the trigger and the spring-loaded turret snaps out to its indexing position. Select the desired position from the color-coded nameplate and rotate the turret to aline the selected positioner with the index. Depress the turret until flush, and the turret will automatically lock into place. To prevent further indexing, insert lockwire through the hole provided in the trigger.

To crimp a terminal, select the proper size and type terminal and insert the prepared wire into the contact pocket until the wire seats on the bottom. The wire should be visible through the inspection hole and the insulation should enter the contact insulation support. Insert the contact and wire into the terminal crimping tool, making sure that the contact is properly seated in the positioner. Actuate the crimping tool handles to crimp the contact and wire. At the completion of the stroke the ratchet releases; open the handles and remove the crimped contact from the tool.

Inspect the crimped terminal and wire. The wire must be visible through the inspection hole. The insulation must be inside the insulation support. The crimping indents must be positioned between the inspection hole and the front of the insulation support. The contact must not be bent. The crimped contact is now ready to be installed into a connector.

For eyeball crimping, remove the head assembly from the tool. Select the proper wire size and move the thumb button until the pointer is alined with the selected wire size

13317

AE.39

Figure 7-14.–Crimping tool MS 3191-3.

on the indentor gap selector plate. Holding the contact in the crimping tool, slowly close the handles and at the same time position the contact so that the indentors are positioned midway on the contact barrel. Insert the wire, making sure it is bottomed in the contact, then close handles fully.

After releasing the handles, remove and inspect the crimped contact. The contact must not be fractured, and the conductor must be visible in the inspection hole.

DIAGONAL PLIERS

Diagonal pliers are described briefly in Basic Handtools, NavPers 10085-A. The following discussion describes a modification which is advantageous when the diagonal pliers are used in the maintenance of equipment aboard aircraft where working clearances are likely to be close.

The diagonal pliers (fig. 7-15) have been modified by adding potting compound to the jaws. This prevents loss of small pieces of wire into the equipment when cutting wire. The potting compound also allows the technician to cut the wire without holding onto the piece being cut away. (Figure 7-15 (A) shows the diagonals before being modified.) If you do not have a pair of these modified diagonal pliers, manufacture your own by adding potting compound. Before applying the potting compound, clean the diagonals with solvent; then secure the handles with a rubberband (fig. 7-15 (C)) and apply the compound. Allow 24 hours for the compound to dry. The jaws may be separated by slicing them apart with a single edge razor blade.

13318

AT.80

Figure 7-15.–Diagonal pliers. (A) Without compound; (B) with compound; (C) applying compound.

SAFETY WIRING PLIERS

When installing equipment in aircraft, it becomes necessary to lockwire (usually referred to as safety wire) designated parts of the installation. The process of lockwiring can be accomplished faster and neater with the use of special pliers. However, the use of these pliers requires extreme care. The wire must be installed snugly, but not so tight that the part of the wire is overstressed. The routing of the twisted wire is prescribed by the particular installation, and in many instances is designated in the appropriate Maintenance Instructions Manual.

Safety wiring pliers (fig. 7-16) are three-way pliers, which hold, twist, and cut. They are designed to reduce the time used in twisting safety wire on nuts and bolts. To operate, grasp the wire between the two diagonal jaws, and the thumb will bring the locking sleeve into place. A pull on the knob twirls the twister, making uniform twists in the wire. The spiral rod may be pushed back into the twister without unlocking it, and another pull on the knob will give a tighter twist to the wire. A squeeze on the handle unlocks the twister, and the wire can be cut to the desired length with the side cutter. The spiral of the twister should be lubricated occasionally.

MECHANICAL FINGERS

Small articles which have fallen into places where they cannot be reached by hand may be retrieved with the mechanical fingers. This tool is also used when starting nuts or bolts in difficult areas. The mechanical fingers (fig. 7-17) have a tube containing flat springs which extend from the end of the tube to form claw-like fingers, much like the screw holder. The springs are attached to a rod that extends from the outer end of the tube. A plate is attached to the end of the tube, and a similar plate to be pressed by the thumb is attached to the end of the rod. A coil spring placed around the rod between the two plates hold them apart and retracts the fingers into the tube. With the bottom plate grasped between the fingers and enough thumb pressure applied to the top plate to compress the spring, the tool fingers extend from the tube in a grasping position. When the

13319

AT.81

Figure 7-16.–Safety wiring pliers.

AT.82

Figure 7-17.–Mechanical fingers.

thumb pressure is released, the tool fingers retract into the tube as far as the object they hold will allow. Thus, enough pressure is applied on the object to hold it securely. Some mechanical fingers have a flexible end on the tube to permit their use in close quarters or around obstructions.

NOTE: Mechanical fingers should not be used as a substitute for wrenches or pliers. The fingers are made of thin sheet metal and can be easily damaged by overloading.

STEEL SCALE

The steel scale (fig. 7-18) is a measuring device that will usually be found in a toolbox. It is graduated in divisions of 1/8 and 1/16 inch on one side and 1/32 and 1/64 inch on the other side. The steel scale most commonly used is 12 inches long.

Measurements are taken with a steel scale by holding it on its edge on the surface of the subject being measured. This will prevent making errors which might be caused by the thickness of the scale. Such thickness causes the graduations to be a slight distance away from the surface of the object. Measurements are read at the graduation which coincides with the distance to be measured.

FLASHLIGHT

Each toolbox should have a standard Navy vaporproof two-cell flashlight. The flashlight is used constantly during all phases of maintenance. Installed in both ends of the flashlight are rubber seals which keep out all vapors. The flashlight should be inspected periodically for the installation of these seals, the spare

13320

AT.83

Figure 7-18.–Steel scale.

bulb, and red lens which are contained in the end cap. NOTE: Do not throw away the red lens; it will be necessary during night operations.

INSPECTION MIRROR

There are several types of inspection mirrors available for use in aircraft maintenance. The mirror is issued in a variety of sizes and may be round or rectangular. The mirror is connected to the end of a rod and may be fixed or adjustable. (See fig. 7-19.)

The inspection mirror aids in making detailed inspection where the human eye cannot directly see the inspection area. By angling the mirror, and with the aid of a flashlight, it is possible to inspect most required areas.

TOOL KITS, SHOP TOOLS, AND TOOL CRIBS

One of the first steps taken when a new man reports for duty in a squadron or activity is to issue him an individual toolbox. The toolbox should contain the low-cost, high-usage handtools that will enable him to perform the tasks assigned. The purpose of the individual handtool kit is to make the necessary tools for performance of line and/or hangar maintenance immediately available to the individual. The contents of the individual handtool kit are among the tools listed in Consumable General Support Equipment for All Types, Classes, and Models of Aircraft, NavAir 00-35QG-016.

Under the crew leader concept of maintenance, the crew leader's kit has the same type tools as the individual handtool kit. It is issued to an individual of a crew, and is to be used by all members of that crew. Thus, the crew leader's handtool kit will have several of the same type and/or size tool where the individual kit has only one.

Shop tools are the larger, low-usage, and special tools for use on specific equipments. A shop tool bin is normally utilized to make available those special tools and medium-usage tools needed to perform the various phases of shop maintenance. However, shop tools also include any handtools required to perform more extensive maintenance than can be accomplished from a toolbox or a crew leader's kit. To determine the types and number of shop tools allowed, refer to the applicable allowance list from the NavAir 00-35QG-0 series.

Frequently, a squadron tool crib has the responsibility for all tools in the squadron, including issuance of tools, inventory of toolboxes, and ordering new tools for replacement of broken or lost tools. A squadron tool crib is set up under the responsibility of the maintenance department. Its purpose is for the stowage and issuance of low-usage handtools and those which are common to more than one shop. Special tools provided by the aircraft manufacturer are also stowed in the tool crib. A complete list of these special tools can be found in the Maintenance Instructions Manual, section one, for each type aircraft.

The tools used in an aircraft maintenance activity are determined by the mission of the activity and the type aircraft to be maintained. In view of this, there is no hard and fast rule as to the type and/or number of tools that may be supplied in the different handtool kits and cribs. The quantity and types of tools allowed for an activity may be found in the appropriate allowance list.

13350

UNIT I - INTRODUCTION

Sketching Freehand Lines — Lesson 3

OBJECTIVE: To learn how to sketch freehand lines.

RELATED INFORMATION:

In order to properly sketch freehand lines, remember to relax and hold the pencil with freedom and not close to the point. In drawing any straight line, be it vertical or horizontal, keep the eyes on the point to which the line is to go rather than on the point of the pencil. Do not try to draw the whole length of a line in a single stroke. It may be an aid to draw a very light line first and then correct the direction of the light line with the finished line without rubbing out the light line. Do not be too disturbed by any waviness, for the accuracy of direction is more important than the smoothness of the line. Once more bear in mind that practice and experience alone will enable you to be a better sketcher. This is important in the field of drafting, for oftentimes you will be called upon to quickly sketch a drawing rather than make a formal instrument drawing.

THIS IS A SAMPLE OF MY LETTERING.

AIRCRAFT HARDWARE

MOUNTING PARTS

Items of hardware used when installing equipment in aircraft are specified in the applicable Maintenance Instructions Manual. In all instances, the proper parts should be used; if substitution becomes necessary, care must be taken that the substitute item is satisfactory in all respects.

It is not always desirable to use the same mounting parts that were removed from the installation. Prior to reinstalling the same items, an inspection must be made to insure that the parts are of the type specified, and are not defective or damaged. It must also be determined that instructions do not forbid their reuse. Then, and only then, may the removed parts be reinstalled.

General information regarding such mounting parts as screws, nuts, bolts, washers, etc., is included in the Rate Training Manual Airman, NavPers 10307-B. Aircraft Structural Hardware for Aircraft Repair, NavWeps 01-1A-8, is a valuable source for detailed information.

Substitution of Parts

If the specified mounting parts cannot be obtained, a temporary installation may be made using suitable substitute parts; but these parts should be replaced with the proper items as soon as they can be obtained. When making parts substitutions, special attention must be given to the following considerations:

1. Corrosion. The chemical or metallic composition of the part must be such that its use does not contribute appreciably to the danger of corrosion.

2. Strength. The strength of the substitute part must be the same, or greater than the ones prescribed. (When determining the strength, consideration should be given to the tensile, compression, and/or shear strength, as applicable to the specific use.)

3. Size. Substitute bolts and screws should be the same size as the prescribed item. If a detachable nut is to be used, a different thread may be tolerated; if a threaded hole or an anchor nut is involved, the thread must be the same as the one prescribed. In all cases, washers must have the same inner diameter as the prescribed item, but a different outer diameter or thickness may sometimes be permitted.

4. Length. Substitute screws or bolts must have a length which is sufficient for the particular installation, but must not be so long that they are in the path of any moving part. They must not be in contact with other aircraft items such as electrical wiring, hydraulic lines, etc.

5. Magnetic properties. Specific areas of the aircraft (for example, vicinity of such items as the magnetic compass, magnetic anomaly detection equipment, radio direction finder, or gyros) should not be changed in a manner that

188 13322

may cause the magnetic fields of the area to become distorted. In these areas, any substitute part must possess the same magnetic properties and characteristics as the one prescribed.

6. Style. Most items of mounting hardware are available in various styles. It is easy to find screws and bolts which are identical in all respects except for the type head. These parts are usually to be preferred as substitutes, provided they possess all required special features.

7. Special features. If a bolt is to be torqued to a given value, a torque wrench which is usable with that type part and which has the proper torque range must be available. If lockwiring is required, the part must have suitable provisions.

8. Lubrication or coating. If specific instructions call for lubrication or coating of the parts, they must be followed for the substitute part as well as for the prescribed part. If no lubrication is permitted, the substitute part is not to be lubricated.

TURNLOCK FASTENERS

Turnlock fasteners are used to secure inspection plates, doors, and other removable panels on aircraft. Turnlock fasteners are also referred to by such terms as quick-opening, quick-action, and stress panel fasteners. The most desirable feature of these fasteners is that they permit quick and easy removal of access panels for inspection and servicing purposes.

Turnlock fasteners are manufactured and supplied by a number of manufacturers under various trade names. Some of the most commonly used are the Camloc stress-panel fastener and Airloc, both of which are discussed in this section. Other turnlock fasteners are covered in the Rate Training Manual Airman, NavPers 10307-B.

Camloc Stress-Panel Fasteners

The Camloc stress-panel fastener (fig. 7-20) is a high-strength, quick-release, rotary

1. Tension spring.
2. Stud assembly.
3. Bushing.
4. Retaining ring.
5. Receptacle assembly.
6. Receptacle attaching rivets.
7. Outer skin.
8. Inner skin.
9. Insert
10. Cover.

AT.85

Figure 7-20.—Camloc stress-panel fastener.

type fastener and may be used on flat or curved, inside or outside panels. The fastener may have either a flush or nonflush stud. The studs are held in the panel with flat or cone-shaped washers, the latter being used with flush fasteners in dimpled holes.

This fastener may be distinguished from screws by the deep No. 2 Phillips recess in the stud head and by the bushing in which the stud is installed. A threaded insert in the receptacle provides an adjustable locking device. As the stud is inserted and turned counterclockwise 1/2 turn or more, it screws out the insert sufficiently to permit the stud key to engage the insert cam when turned clockwise. Rotating the stud clockwise 1/4 turn engages the insert; and continued rotation screws the insert in, tightening the fastener. Turning the stud 1/4 turn counterclockwise will then release the stud but will not screw the insert out far enough to permit reengagement in installation. It is necessary to turn the stud at least 1/2 turn counterclockwise to reset the insert.

To unlock the stress-panel fastener and reset it in the same operation, use a No. 2 Phillips screwdriver (or equivalent), turning the stud counterclockwise 1/2 turn or more. Do not turn the stud past stop.

CAUTION: Do not use a power screwdriver on this fastener.

To lock use a Phillips No. 2 screwdriver (or equivalent) push the stud in and turn clockwise until increased torque is felt; then continue turning until the fastener is tight.

NOTE: When installing a large panel, it may be necessary to engage all the fasteners before tightening. This is done by pushing each stud in and turning it clockwise 1/4 turn. The stud should engage the receptacle but remain loose. If the stud does not engage, it will pop out, indicating that the insert must be reset by turning the stud counterclockwise 1/2 turn or more.

Airloc Fastener

The Airloc fastener consists of a stud, stud cross pin, and a receptacle. (See fig. 7-21.) The stud is attached to the access cover, and is held in place by the cross pin. The receptacle is riveted to the access cover frame. A quarter turn of the stud (clockwise) locks the fastener in place, and turning the stud counterclockwise unlocks the fastener.

THREADED FASTENERS

Threaded fasteners are covered in the Rate Training Manual Airman, NavPers 10307-B. However, a brief discussion of a new development in threaded fasteners is included in this text.

"Torq-Set" Screws

"Torq-Set" machine screws (offset cross-slot drive) have recently begun to appear in new equipment. The main advantage of the newer type is that more torque can be applied to its head while tightening or loosening than any other screw of comparable size and material without damaging the head of the screw.

Torq-Set machine screws are similar in appearance to the more familiar Phillips machine screws.

Since a Phillips driver could easily damage a Torq-Set screwhead, making it difficult if not impossible to remove the screw even if the proper tool is later used, maintenance personnel should be alerted to the differences. (See fig. 7-22.)

ACCOUNTABILITY

A definition of the word accountability is "the state or quality of being responsible–a charge (object) for which one is responsible or accountable." The Navy has a code that is called Material Accountability Recoverability Codes (MARC's). These codes appear in column 3 of the Section G Allowance List, NavAir 00-35-QG-0 Series and are illustrated by the following examples:

Code:

B—Exchange consumables—requiring old items for replacement items such as items containing precious metal, highly pilferable items, or certain high cost items. Example: Drill, electric portable, FSN 9Q 5130-226-5384.

C—Consumables—expendables. Example: Stripper, wire, FSN 9Q 5110-268-4220.

13324

AT.86

Figure 7-21.–Airloc fastener.

ALLOWANCE LISTS

Allowance lists are lists of equipments, material, and/or tools made available to an organization for performance of maintenance.

NavAir 00-35QG-0 Series

These allowance lists contain allowances of shop and general support equipment and material which will be made available for maintenance support of aircraft as may be assigned or supported by the following levels of maintenance:

1. Intermediate level (shop).
2. Organizational level (hangar/line).
3. Advanced base components, excluding Aircraft Fleet Marine Force activities supported by tables of basic allowances.

CUSTODIAL RESPONSIBILITY

Most handtools are not feasibly repairable. Due to this fact and their original low cost (compared to shop tools), they are classed as consumable. However, the activity must pay for replacements. Therefore, it is the duty of each individual to help eliminate the need for replacements. One method of accomplishing this is by carrying an inventory of tools in your toolbox so that upon completion of a job you can be sure that all of the tools are ac-

13325

AT.87

Figure 7-22.—Comparison of Phillips and Torq-Set screwheads.

counted for. A tool that has been lost represents a waste of funds; in addition, it is a definite liability. If it has been left loose in an aircraft, it can become a dangerous missile when the aircraft is launched or when the aircraft is performing violent maneuvers.

Inventory Requirements

The basic objective of an inventory is to insure a proper balance between the supply of, and the demand for, those tools required for the efficient operation and maintenance of a squadron or maintenance activity. To accomplish this objective it is necessary that tools be identified and cataloged to provide accurate knowledge of the tools being used. Each item should be accounted for every 30 to 90 days in accordance with squadron instructions. The number of handtools on hand in relation to the number required by the activity should be indicated by the inventory.

Reordering Tools

Tools are reordered as the inventory requirements dictate. Usually the senior petty officer or his delegate reorders all tools—both shop tools and those for individual toolboxes, as they are needed. However, squadron or maintenance activity policy is followed in all cases.

It is unwise to wait until the number of tools needed is too large, as it is easier for the supply department to fill a small order rather than a large one.

Tools are ordered by reference to Consumable General Support Equipment for All Types, Classes, and Models of Aircraft, NavAir 00-35QG-016.

13326

CHAPTER 8

ELECTRONIC TEST EQUIPMENT

Other chapters of this manual discuss the basic principles and concepts of some of the equipment which the technician may encounter. An understanding of the theory of operation of these equipments forms only a portion of the knowledge necessary to successfully perform the maintenance tasks required. A thorough knowledge of electrical and electronic test equipment is also needed.

All electronic test equipment is designed and constructed to perform tests of one or more specific types. These tests are used to determine the proper operation or alinement of electronic sets, circuits, or parts. The performance of electronic ASW units in the aircraft is determined by the accuracy of the test equipment used to calibrate and aline them and the care with which the technician performs these jobs. Without test equipment very few electronic devices could be used; therefore, it follows that every technician should learn to use test equipment properly.

The test equipments discussed in this chapter are typical of the ones currently in use in the fleet. No attempt is made to include theory beyond that necessary to describe the operation of the test set under discussion. Whenever the technician must use a piece of test equipment with which he is not familiar, he should always consult the appropriate instruction manual. These publications contain detailed and specific information on the particular equipment. The purpose of this chapter is to discuss some of the different test equipments from the standpoints of operation and general operational and maintenance procedures.

CARE AND USE OF TEST EQUIPMENT

All electronic maintenance shops are provided with a variety of test equipment to be used in maintaining the many different types of electronic units its supports. However, there are very few spare test sets. When a test set becomes inoperative, shop maintenance suffers. Therefore, every man must use the test equipment only for the purposes and in the manner for which it was designed. Protect the equipment from physical harm that may result from dropping, falling, or any other careless misuse, and always observe proper operating techniques.

One of the chief causes of test set failure is carelessness. The user can be careless in operating procedure or in handling the set. The usual carelessness in operating procedure is improper selection of range for the quantity to be measured, such as attempting to measure 250 volts on the 50-volt scale of a meter. If there is any doubt about proper usage of a test set, it is wise to refer to the manual issued with the set.

Much damage to test equipment results from improper handling. Technicians often place test sets near the edge of the bench where they can easily be knocked off or pulled off by the test leads. Read the instructions for proper handling and operating procedure, and think while using the equipment.

CALIBRATION

Most test sets require occasional checks to determine if they are within operating tolerances. Some test sets are used as frequency standards and require periodic calibration. In every case the recommendations of the manual

or pamphlet issued with the set should be followed, unless those recommendations have been changed by current instructions.

Calibration is normally performed in a shop that is equipped with special purpose test sets. It is seldom accomplished at the organizational level of maintenance.

REPAIR

Minor repair of test sets is often accomplished at the organizational level of maintenance. When calibration of the set is not involved. Repairs are usually limited to replacement of test leads and fuses. Current instruction on repair of test equipment should be consulted before attempting any repairs of a major nature.

HANDLING PRECAUTIONS

Some equipments may require special handling; however, there are several precautions which apply to test equipments in general. Rough handling, moisture, and dust all affect the useful life of such devices. Bumping or dropping a test instrument, for example, may destroy the calibration of a meter or short circuit the elements of an electronic tube within the instrument. Creasing or denting coaxial test cables will alter their attenuating effect, thereby affecting the accuracy of any RF measurements made with these cables in the circuit.

To reduce the danger of corrosion to untreated parts, always store test equipment in a dry place when it is not in use. Excessive dust and grime inside a test equipment also affects its accuracy. Be sure that all the assembly screws which hold the case of the test equipment in place are tightened securely. As an added precaution, all dust covers should be placed on test equipments when they are not in use.

Meters are the most delicate parts of test equipments. In order to insure that the meter will maintain its accuracy, these additional precautions should be followed:

1. Make certain that the amplitude of the input signal under test is within the range of the meter.
2. Keep meters as far away as possible from strong magnets.
3. When servicing an item of electronic equipment which contains a meter, disconnect the meter from the circuit before making resistance or continuity tests.

(The latter precaution will eliminate the possibility of burning out the meter.)

The instructions for properly stowing test equipment cables and other accessories, as set forth in the instruction manuals accompanying the equipment, should be carefully read and strictly followed. Improper stowage of accessories results in changes in cable characteristics, intermittent shorts in cables and leads, and, in general, causes unreliable test equipment indications.

MEASURING INSTRUMENTS

The term "measuring instruments," as used in this discussion, includes only that class of test equipments which measure the basic parameters of an electronic equipment. The basic parameters are (in this application) voltage, current, resistance, power, frequency, and field intensity.

The discussion of measuring instruments includes test equipment classes designated as multimeters, electronic voltmeters, power measuring devices, frequency meters, and field intensity measuring devices.

REVIEW OF METER OPERATION

There must be some source of power available to operate a meter. Some meters are powered by batteries installed in the meter case, others are supplied through an electrical power cord which is plugged into a power receptable; a vacuum tube volt meter (VTVM) is an example of the latter type. The power to operate some meters (such as the megger) is produced by manual operation of a handcrank. Each of these three types are described in the following paragraphs.

Most meters are designed to be used for measuring more than one electrical quantity, and are called multimeters. Before discussing any one particular type meter, a brief review of each of the basic meters is presented.

Ammeter

The amplitude of current flow through the basic meter mechanism limits it to measuring a fixed range of only a fraction of an ampere. To

18328

overcome this limitation, and to protect the mechanism, a current shunt is used. This device, which is actually a resistance of low value, permits the instrument to serve as a d-c ammeter in the measurement of relatively large direct currents.

The current distribution between meter movement and shunt is inversely proportional to their individual resistances. Thus, the shunt (which has less resistance) carries the majority of the current. Since the meter coil carries only a small portion of the circuit current, it is capable of indicating relatively large values of circuit current. The instrument may be adapted to a variety of current ranges by the use of shunts of different values which are switched in or out as required. Figure 8-1 shows a simplified schematic diagram of an ammeter-section taken from a typical volt-ohm-milliammeter.

Ohmmeter

For any given ohmmeter, midscale deflection is obtained when the current drawn by the meter is one-half the value of the current at full-scale (zero ohms) deflection. This condition exists when the resistance being measured is equal to the total meter circuit resistance. Analysis of the circuit in figure 8-2, shows the full-scale deflection is obtained when the meter probes are shorted together, and that less than full-scale deflection is obtained when the resistance to be measured, R_X, is connected into the circuit. If the meter now reads one-half of its former current, it follows that the total curcuit resistance has doubled, indicating that R_X is equal to the total meter circuit resistance.

Since the ohms-calibrated scale is nonlinear, the midscale portion represents the most accurate portion of the scale. However, the usable range extends with reasonable accuracy on the high end to ten times the midscale reading, and on the low end to one-tenth of the midscale reading.

To extend the range of an ohmmeter, the proper values of shunt and series resistors and battery voltages are connected into the circuit so that with the test leads shorted the meter will read full scale. Figure 8-3 shows a simplified schematic diagram of an ohmmeter section taken from a typical volt-ohm-milliammeter.

Voltmeter

To make the basic meter mechanism suitable for measuring d-c voltages, the voltage multiplying resistor is added. The voltage multiplying resistor is placed in series with the coil (fig. 8-4) and limits the flow of current to a safe value.

Since the value of the resistor is constant for any given application, the flow of current

AT.88

Figure 8-1.–Simplified schematic diagram of an ammeter.

Figure 8-3.–Simplified schematic diagram of an ohmmeter.

through the coil is proportional to the voltage under measurement. By proper calibration of the dial, the instrument may be made to indicate voltage although it is actually activated by currents. In practice, the voltage ranges of the instrument are established by the use of different values of multiplying resistors.

NONELECTRONIC METERS

Much of the technician's work requiring the use of a volt-ohm-milliammeter can be accomplished with a portable, battery operated multimeter. Many shops employ the TS-352, Simpson 260, or the PSM-4 for field use (troubleshooting in the aircraft, for instance). The technician will, however, often need a more sensitive meter–one that gives more accurate readings and has wider ranges.

Equipment schematics and wiring diagrams often specify that voltages indicated at test points were obtained by using a meter of a certain sensitivity, such as a 20,000-ohms-per-volt meter. A meter of the same sensitivity should be used when repairing that equipment in order to obtain accurate readings.

AT.91

Figure 8-4.–Simplified schematic diagram of a d-c voltmeter.

Multimeter AN/PSM-4C

This multimeter is a portable, general purpose, nonelectronic instrument designed for general electrical and electronic service and maintenance functions. Multiple ranges are provided for resistance, a-c and d-c voltages, and current. Test results are indicated directly on a wide-faced panel meter. It employs a 20,000-ohms-per-volt movement to provide accurate measurement on low voltage ranges.

Range and function selectors and a meter adjusting control are provided. This meter is designated as a replacement for the TS-352 series multimeters, although the older type is still in fairly common usage.

Milliohmmeter AN/USM-21A

The AN/USM-21A low range ohmmeter can measure resistances in the range of 10 milliohms or less. Most ohmmeters read zero at such a low value. Several troubleshooting problems can be solved easily with such an instrument. One of the most common and troublesome is to find the exact location of a short circuit in a power distribution circuit involving many parallel paths.

In using the milliohmmeter, several problems are encountered. These problems include stray circuit resistances such as contact resistance, test lead resistance, and switching resistance. In using the conventional low range ohmmeters, the primary limitation is in the contact resistance at the test probes.

The AN/USM-21A was designed principally to overcome the contact resistance problem.

ASSIGNMENT: Use the figure shown above as a model.

1. On the sheet of graph paper issued to you, start at a point 2" from the top border and $\frac{1}{2}$" from the left-hand border and proceed to sketch the horizontal lines freehand.

2. At a point 2" from the top border and 4" from the left-hand border, draw the vertical lines freehand. Use the same paper.

3. On the bottom portion of the paper, letter the following $\frac{1}{4}$" high.

   THIS IS A SAMPLE OF MY LETTERING.

   YOUR NAME _____ DATE _____

   YOUR ADDRESS _____ YOUR SCHOOL _____

A measured current is passed through the test circuit by means of a heavy set of clip leads. Using an auxiliary set of test leads which carry very little current, the resulting voltage drop across the test circuit is measured by a sensitive millivoltmeter which senses this voltage.

Megger

A megger is an instrument that applies a high voltage to the component under test and measures the current leakage of the insulation. Thus a capacitor or insulated cable can be checked for leakage under much higher voltages than an ohmmeter is capable of supplying. It consists of a hand-driven, d-c generator and an indicating meter. The name megger is derived from the fact that it measures resistances of many megohms.

There are various resistance ratings of meggers with full-scale values as low as 5 megohms, and as high as 10,000 megohms. Figure 8-5 shows the scale of a 100-megohm, 500-volt megger. Notice that the upper limit is infinity and that the scale is crowded at the upper end. The first scale marking below infinity represents the highest value for which the instrument can be accurately used. Thus, if the pointer goes to infinity while making a test, it means only that the resistance is higher than the range of the set.

There are also various voltage ratings of meggers (100, 500, 750, 1,000, 2,500 etc.). The most common type is the one with a 500-volt rating. This voltage rating refers to the maximum output voltage of the megger. The output voltage is dependent upon the speed of turning of the crank and armature. When the megger's armature rotation reaches a predetermined speed, a slip clutch will maintain the armature at a constant speed. The voltage rating is important, for the application of too high a voltage to even a good component will cause a breakdown. In other words, do not use a 500-volt megger to test a capacitor rated at 100 volts.

Meggers are used to test the insulation resistance of conductors in which shorting or breaking down under high voltage is suspected. In some situations, meggers are used in the prevention of unnecessary breakdowns by maintaining a record of insulation resistance of power and high voltage cables, motor and generator windings, and transmission lines. These records will reflect fluctuations in resistance and aid in determining when the components should be replaced to prevent a breakdown.

Meggers are used for testing capacitors whose peak voltages are not below the output of the megger. They are also used for testing for high resistance grounds or leakage on such devices as antennas and insulators.

Precautions to be followed in the use of the megger are as follows:

1. When making a megger test, the equipment must not be energized. It must be disconnected entirely from the system before it is tested.

2. Observe all rules for safety in preparing equipment for test and in testing, especially when testing installed high voltage apparatus.

3. Use well-insulated test leads, especially when using high range meggers. After the leads

AT.92

Figure 8-5.–Scale of 100-megohm, 500-volt megger.

043331

are connected to the instrument and before connecting them to the component to be tested, operate the megger and make sure there is no leak between the leads. The reading should be infinity. Make certain the leads are not disconnected or broken by touching the test ends of the leads together while turning the crank slowly. The reading should be approximately zero.

4. When using high range meggers, take proper precautions against electric shock. There is sufficient amount of capacitance in most electrical equipment to "store up" sufficient energy from the megger generator to give a very disagreeable and even dangerous electric shock. Owing to a high protective resistance in the megger, its open circuit voltage is not as dangerous, but care should be exercised.

5. Equipment having considerable capacitance should be discharged before and after making megger tests in order to avoid the danger of receiving a shock. This can be accomplished by grounding or short circuiting the terminals of the equipment under test.

ELECTRONIC METERS

Electronic meters are used primarily for the same purposes as are the nonelectronic meters. Some characteristics of their operation, however, give them definite advantages. In the electronic multimeter, the current and resistance measuring circuits function in a manner identical to the corresponding nonelectronic measuring instruments. The measurement of voltage, however, involves the use of an amplifier which in turn requires that the meter be calibrated prior to use.

Proper calibration and use of the instruments vary slightly according to model. Details are included in the Operation Instruction Manual for each model.

The ordinary voltmeter has several disadvantages that make it practically useless for measuring voltages in high impedance circuits. For example, suppose that the plate voltage of a pentode amplifier is to be measured. (See fig. 8-6.) When the meter is connected between the plate and cathode of the electron tube, the meter resistance R_m, is placed in parallel with the effective plate resistance R_{eff}, thereby lowering the effective plate resistance. The effective plate resistance is in series with the plate load resistor, R_L, and this series circuit appears across the supply voltage, E_{bb}, as a voltage divider. Since the overall resistance is lowered, it follows that current through R_L will also increase, the voltage drop across R_L will also increase, and the voltage drop across R_{eff} will decrease. The result is an incorrect indication of plate voltage, and is called loading effect.

Calculation of Loading Effects

Before the voltmeter is connected, the plate current is determined by the effective resistance of the plate circuit, the plate load resistor, and the plate voltage. If the tube has an effective resistance of 100,000 ohms, a plate load resistance of 100,000 ohms, and the plate power supply is constant at 200 volts, then the plate current is

$$\frac{200\text{v}}{200{,}000\Omega}$$

or 0.001 ampere. The plate voltage (plate to cathode) is 0.001 x 100,000, or 100 volts.

Assume that the voltmeter used to measure the plate voltage of the tube has a sensitivity of 1,000 ohms per volt and that the selected meter range is from 0 to 250 volts. The meter will then have a resistance of 250,000 ohms. This resistance in parallel with the tube resistance of 100,000 ohms produces an effective resistance of 71,400 ohms in series with the plate load resistor. The total resistance across the

AT.93

Figure 8-6.–Loading effect created by meter resistance.

133:2:E1

B supply is therefore 171,400 ohms instead of the 200,000 ohms before the meter was applied, and the current through the plate load resistor is

$$\frac{200\ v}{171{,}400\Omega},$$

or 0.00117 ampere. Across the plate load resistor the voltage drop is 0.00117 x 100,000, or 117 volts, and the plate-to-cathode voltage on the tube is 200-117, or 83 volts when the meter is connected, thus causing an error of 17 volts. The lower the sensitivity of the meter, the greater the error will be; in this example, the error of 17 volts when the reading should be 100 volts is a 17 percent error.

A meter having a sensitivity of 20,000 ohms per volt and a 250-volt maximum scale reading would introduce an error of about 1 percent. However, in circuits where very high impedances are encountered, such as in grid circuits of electron tubes, even a meter of 20,000 ohms per volt sensitivity would impose too much of a load on the circuit.

VTVM Advantages

Another limitation of the alternating current, rectifier type voltmeter is the shunting effect at high frequencies of the relatively large capacitance of the meter's rectifier. This shunting effect may be eliminated by replacing the usual metallic oxide rectifier with a diode electron tube; the output of the diode is applied to the grid of an amplifier in which the plate circuit contains the d-c meter. Such a device is called an electron tube voltmeter or a vacuum tube voltmeter, usually abbreviated VTVM. Voltages at frequencies up to 500 megahertz, and sometimes even higher, can be measured accurately with this type of meter. The frequency limitation is determined by the model of VTVM.

The input impedance of a VTVM is large, and therefore the current drawn from the circuit whose voltage is being measured is small and in most cases negligible. The main reason for using a vacuum tube voltmeter is to overcome the loading effect by taking advantage of the VTVM's extremely high input impedance. A VTVM that is used extensively for electronics maintenance is contained in the TS-505 multimeter.

Vacuum Tube Voltmeter TS-505

Figure 8-7 shows a front panel view of the TS-505. The VTVM measures d-c voltages from 0.05 volt to 1,000 volts (in 9 ranges), and a-c voltages from 0.05 volt to 250 volts rms (in 7 ranges), at frequencies from 30 Hz to 1 MHz. With the RF adapter that is used with the d-c voltage measurement circuit, RF voltages may be measured from 0.05 volt to 40 volts rms at frequencies from 500 kHz to 500 MHz. D-c resistances from 1 ohm to 1,000 megohms may be measured.

The accuracy of this meter is good, being 5 percent for d-c voltages and 6 percent for a-c and RF voltages. The meter movement requires 1 ma for full-scale deflection.

The input impedance to the meter is 6 megohms at audiofrequencies, 40 megohms on

AT.94

Figure 8-7.–TS-505 multimeter, front panel.

13333

the 1,000-volt d-c range, and 20 megohms on all other ranges.

The power requirement is 98 to 132 volts, single phase, 50 to 1,000 Hz, at about 21 volt-amperes.

The removable cover of the TS-505 contains accessories such as alligator clips, an RF adapter, and miniature probe tips. The miniature tips slip over the regular tips when working in confined areas.

OPERATING CONTROLS.–The controls that you will use when operating the meter (fig. 8-7) are as follows:

1. FUNCTION switch: Selects the type of multimeter operation desired and turns the multimeter on or off.

2. RANGE switch: Selects various voltage or resistance measurement ranges.

3. ZERO ADJ. control: Controls pointer of indicating meter. Used to set the meter pointer at zero on the +DC, -DC, AC, or OHM scale, or at midscale on the ±DC scale.

4. OHMS ADJ. control: Controls pointer of indicating meter. Used to set the meter pointer at ∞ on the OHMS scale when the FUNCTION switch is set on OHMS position.

5. Meter: Indicates the value of voltage or resistance measured.

6. AC LINE cord: Connect multimeter to a-c power source.

7. COMMON probe: Connects the ground, or common circuit of the multimeter, to the equipment under test.

8. DC probe: Connects equipment under test to the d-c measuring circuit of the multimeter.

9. OHMS probe: Connects equipment under test to the ohmmeter circuit of the multimeter.

10. AC probe: Connects equipment under test to the a-c measuring circuits of the multimeter.

11. Pilot light indicator: Lights when power is applied to the multimeter.

TECHNIQUES FOR USE.–The operation of this meter is virtually self-explanatory. By studying the controls and their respective markings, you should be able to determine the steps to follow when making a particular measurement. Do not attempt to use this instrument unless you have studied the technical manual which sets forth the operating procedures, or unless you have been instructed in its proper usage, under the direction of your shop supervisor.

Two peculiarities of this meter are:

1. In order for it to indicate accurate readings it must warm up. This usually takes about 10 minutes. During this period the meter pointer may drift rapidly; this is normal.

2. Voltage measurements cannot be read directly on the meter scale when the function switch is set at the ±DC position.

The purpose of the ±DC position (zero center scale) is to determine the polarity of an unknown d-c voltage or to indicate a zero d-c voltage input to the multimeter.

CAUTION: The maximum d-c voltage which may be applied to the multimeter when the function switch is set at the ±DC position is one-half of the voltage indicated by the panel marking opposite the range switch setting.

The major difference between any VTVM and a conventional multimeter is that the VTVM utilizes a vacuum tube in its input. For a detailed explanation of the circuitry of the TS-505 VTVM consult the manufacturer's manual or the Operation and Service Instruction Manual.

Phase Angle Voltmeters

The overall accuracy of many electronic equipments is determined by measuring phase angles in computing transformers, computing amplifiers, and resolver systems. In the past, one of the most common methods used for measuring phase shift or phase angles between signals was observing patterns on an oscilloscope. With this method, it was hard to determine small angles, and difficult to translate various points into angles and sines of angles. The most limiting factor in using oscilloscope patterns developed when one of the signals contained harmonic distortion or noise.

In any complex waveform containing a fundamental frequency and harmonics, measuring phase shifts presents problems. In most applications, interest lies in the phase relationship of the fundamental frequency, regardless of the phase relationship of any harmonics which may be present. One of the requirements of a phase measuring device is to measure the phase difference between two discrete frequencies, regardless of the phase and amplitude of other components of the waveform.

The basic block diagram of a phase angle voltmeter is shown in figure 8-8. There are

13334

two inputs–the signal and the reference. Both channels contain filters which pass only the fundamental frequency. All other frequencies are highly attenuated. Each channel has a variable amplitude control and amplifiers to increase the variety of signals that can be checked.

A calibrated phase shifter is inserted into one channel; that channel signal can be phase shifted to correspond to the other channel. This is detected in the phase detector and observed on the meter.

The calibrated phase shifter is made up of a switch (whose position corresponds to the 0°, 90°, 180°, and 270° phase shift) and a potentiometer (whose dial is calibrated from 0° to 90°). The total phase shift is made up of the sum of the two readings.

The phase detector is a balanced diode bridge type demodulator. Its output is proportional to the signal frequency amplitude times the cosine of the angle of phase difference between the signal input and the reference input.

If the reference input is phase shifted until it is in phase or 180° out of phase with the signal input, the output from the phase detector is proportional to the signal input amplitude (the cosine of the angle is unity). If the reference input is phase shifted until it is 90°or 270° from the signal input, the phase detector output is zero (the cosine of the angle is zero).

The point at which the two signals are in phase or 180° out of phase is the point of maximum deflection on the meter. The difference between the in phase and the 180° out of phase points is in the direction in which the needle swings–not the distance it swings. As the point of maximum deflection is approached, the rate of change of the meter reading decreases because the cosine has a small rate of change near 0°. This makes it difficult to read the exact point of maximum deflection.

AT.95

Figure 8-8.–Phase angle voltmeter, block diagram.

Because the cosine has a maximum rate of change as it approaches 90 (and thus gives a better indication on the meter), most commercial voltmeters are set to determine the point at which the signals are 90° out of phase–"quadrature." When the voltmeter is set for this point, there must be some way of converting the phase shifter reading so that it shows the correct amount of phase shift rather than 90°more or less than the actual amount. Some confusion exists in this area because different manufacturers have different methods of determining the signal quadrant. Manufacturers also differ on whether the final reading is a leading or a lagging phase shift. This means the technician must be familiar with as many types of phase angle voltmeters as the Navy has in the field. He cannot assume that the method he uses to determine phase angle on one type of meter can be used on another; nor can he assume that, because one meter gives him a leading angle between signal and reference waveforms, another manufacturer's meter also gives leading phase shift.

Differential Voltmeter

The differential voltmeter is a realible precision item of test equipment. Its general function is to compare an unknown voltage with an internal reference voltage, and to indicate the difference in their values. The differential voltmeter in most common use in Navy applications is the 803D/AD (fig. 8-9), manufactured by the John Fluke Co. The remaining portion of this discussion is based on that instrument.

The 803D/AD is usable as an electronic voltmeter, as a precision potentiometer, and as a megohmmeter. It can also be used to measure the excursions of a voltage about a reference value. Ease of operation, inherent protection from any accidental overload, and high reliability of readings are additional advantages of the instrument. It is accurate enough for precision work in calibration laboratories, yet rugged enough for general shop use.

13335

13334

AT.96

Figure 8-9.–Differential voltmeter, Model 803D/AD.

13336

The heart of the unit is a precision 500-volt d-c reference power supply. This 500 volts can be precisely divided into increments as small as 10 microvolts by means of 5 voltage dials. Unknown a-c or d-c voltages are matched against the precise internal voltage until no deflection occurs on the panel meter. The unknown voltage is then simply read from the voltage dials. In the highest null sensitivity range, a potential difference between unknown and reference voltage as small as 0.01 volts causes full scale meter deflection.

At null, the differential voltmeter presents an "infinite" input impedance to the voltage under measurement, almost completely eliminating circuit loading.

A functional schematic diagram of the differential voltmeter is shown in figure 8-10. The principal circuit divisions are as follows:

1. A 500-volt d-c reference power supply.
2. Precision voltage divider network.
3. VTVM.
4. Chopper-amplifier.
5. Converter and converter power supply.

The system circuitry is designed with two separate common returns. One of these, the return for the converter power supply and reference power supply, provides a safety factor for personnel and a capability for measuring a potential difference between two voltages. The other, which is the common return of the VTVM power supply, is connected to the known reference voltage output from the precision voltage divider network. This arrangement provides a constant d-c voltage of +108 volts across the differential amplifier regardless of the d-c potential applied to the grid.

D-C REFERENCE POWER SUPPLY.–A full wave rectifier with its associated filter network supplies a d-c voltage of approximately 1,000 volts to a conventional electron controlled voltage regulator. The regulated output is maintained at 500 volts ±0.01 percent.

In the 500 V DC position, the RANGE switch (S2E) passes this 500 volts directly to the precision voltage divider. In the 50 V DC, 5 V DC, and 0.5 V DC positions, range resistors S2F divide the reference voltage to 50, 5, and 0.5 volts d.c., respectively. In all a-c positions of the RANGE switch, only 5 volts of the reference supply is used, due to the fact that the maximum output of the a-c to d-c converter is 5 volts.

PRECISION VOLTAGE DIVIDER.–Each of the four precision voltages available from the reference supply must be made adjustable through a precision divider network so that unknown voltages may be nulled or matched exactly. The five decade resistor strings (fig. 8-11) accomplish this function.

Note that each string, with the exception of the first, parallels two resistors of the string that precedes it. Between the two wipers of S4, there is a total resistance of 40K and a total

AT.97

Figure 8-10.–Differential voltmeter, functional schematic diagram.

AT.98

Figure 8-11.–Precision voltage divider.

13337

voltage of 100 volts d.c. with the RANGE switch in the 500 V DC position. Across the wipers of S5, S6, and S7, there are 10, 1, and 0.1 volts d.c., respectively. Switch S8 selects increments of 0.01-volt d.c. from the last decade. These voltages are reduced by a factor of 10 for each successively lower voltage range.

All resistors of each decade are matched and all decades are matched for each instrument, providing an overall divider accuracy of 0.005 percent.

With the NULL switch in any null range, the output of the precision voltage divider appears at the grid of one-half of the VTVM differential amplifier. A one two-hundredths ampere (5 milliampere) fuse protects this output.

VACUUM TUBE VOLTMETER.–When operating in the differential mode, output voltage from the precision voltage divider appears on the grid of V4B, one-half of the differential amplifier. (See fig. 8-12). The unknown voltage appears on the grid of V4A, the other half of the differential amplifier. Any difference between these potentials is indicated by the meter coupled between the cathodes of V4A and V4B. When the output voltage exactly matches the unknown, the meter reads zero and no current is drawn from the source being measured, because the same potential exists on both sides of the input resistances.

When used as a conventional VTVM, the grid of V4B is connected to the 0-volt bus, or negative binding post. With the range switch in the 0.5 V DC position, the unknown voltage appears directly on the grid of V4A and the meter indicates the approximate value of the unknown. Input divider resistors maintain the 0 to 0.5 grid voltage range for all instrument voltage ranges. The input resistance of the instrument in the VTVM position is 10 megohms.

CONVERTER.–All a-c measurements are made by first converting the a-c input to a d-c voltage. The converter provides a maximum d-c output of 5 volts for a maximum a-c input of 5 volts rms. In the 5 V AC position, range switch sections of S2A and S2B couple the converter amplifier input directly to the binding post. In the 50 V AC and 500 V AC positions, input attenuators reduce the unknown a.c. to provide a maximum of 5 volts a-c input to the first converter amplifier.

AT.99

Figure 8-12.–Differential amplifier.

The overall frequency response of the converter is essentially flat from 30 Hz to 10 kHz.

Repair

The procedures for repairing a defective VTVM are basically the same as for any other electronic equipment. The first step is to sectionalize the fault to the circuit responsible for the abnormal operation of the equipment. The second step is to localize the fault. Localization means tracing the fault to the defective part responsible for the abnormal condition.

Some faults, such as burned-out resistors, arcing, shorted transformer, leaky capacitors, or broken wires, often can be located by sight, smell, and hearing. The majority of faults, however, must be localized by checking voltages and

13338

resistances. For further information on trouble-shooting and repair of test equipment, see the manual applicable to the equipment involved, the Handbook of Test Methods and Practices NavShips 91828(A), and the Electronics Installation and Maintenance Book-Test Methods and Practices, NavShips 900,000.103.

POWER MEASUREMENTS

It is often necessary to check the power consumption and the input and output signal power levels of electronic equipment. The determination of d-c power is comparatively simple; the unit of power (the watt) is the product of the potential in volts and the current in amperes. Therefore, a few basic circuit measurements may be taken and the power computed by means of Ohm's law.

To make accurate a-c power measurements, the phase angle of the voltage and current must be considered. The measurement of a-c power is further complicated by the frequency limitations of various power meters. If there is no phase difference, a-c power may be computed in the same manner as d-c power, by determining the average value of the product of the voltage and current.

Electric power at a line frequency of approximately 60 Hz may be measured directly by a dynamometer type wattmeter. This type of meter (discussed in Basic Electricity) indicates the actual power; and therefore, the phase angle of the voltage and current does not have to be determined. Normally, the exact power consumption of equipment is not necessary for maintenance, and a current measurement is sufficient to decide whether the power consumption is within reason.

In the audiofrequency range, power levels have to be determined in the course of routine checks and during corrective maintenance procedures. When working with audiofrequency amplifiers, it is ordinarily easier and more convenient to measure voltage, current, and impedance and then compute the power than it is to measure power directly.

Power measurements for audiofrequency circuits are usually indicated in terms of decibels (db), decibels referenced to 1 milliwatt (dbm), or volume units (vu). The power gain of an amplifier can be expressed in db. The power level of a sinusoidal signal compared to a 1-milliwatt reference is indicated in dbm. The power level of a complex signal, such as voice, music, or multiplexed information, compared to a reference level of 1 milliwatt is indicated in vu.

Many a-c voltmeters have scales calibrated in decibels or voulume units. Such meters are useful for making measurements where direct indication in decibels is desired. However, it must be remembered that these are voltmeters, and that power measurements are not meaningful unless the circuit impedance is known. (The topic of decibels is discussed in some detail in Basic Electronics.)

At radiofrequencies below the UHF range, power is usually determined by voltage, current, and impedance measurements. One common method, used to determine the output power of RF oscillators and radio transmitters, consists of connecting a known resistance to the equipment output terminals, measuring the current flow through the resistance, and then calculating the power as the product of I^2R. Since the power is proportional to the current squared, the meter scale can be calibrated to indicate power units directly. A thermocouple ammeter is usually used for measurement of RF current. The resistor used to replace the normal load is usually specially designed to have low reactance, and has the ability to dissipate the required amount of power. Such resistors are commonly called "dummy loads" or "dummy antennas."

In the UHF and SHF portion of the radiofrequency spectrum, it is usually difficult to accurately measure the voltage, current, and impedance. These basic measurements may change greatly at slightly different points in a circuit, and are appreciably affected by small changes in the placement of parts in the vicinity of the tuned circuits. To measure the output of microwave radio or radar transmitters, test instruments which convert RF power to another form of energy, such as light or heat, can be used to indirectly measure the power. A method which measures the heating effect of a resistor load on a stream of passing air can be used. Accurate measurement of large magnitude power can be achieved by measuring the temperature change of a water load. The most common type of power meter for use in this frequency range employs a bolometer. The bolometer is a loading device that undergoes

13339

13339

changes of resistance as changes in the power dissipation occur. Resistance is measured before and after RF power is applied, and power can be determined by the change in resistance.

Field Intensity and Noise

The magnitude of the electric field of a radio wave at a given point is known as the "field intensity" or "field strength" of that wave, and is usually measured in terms of millivolts or microvolts per meter. The field strength of a radio wave is determined by measuring the RF voltage induced in a receiving antenna. The unit of field strength is the volt per meter; but since the actual values of induced voltage are quite small, the microvolt per meter is a more convenient unit in practical applications.

Several types of test equipment are available for the measurement of field strength and noise. They are known as "radio test sets," "field strength meters," and "radio noise meters." These instruments can be used to indicate either the relative or the absolute magnitude of the field intensity of the energy radiated by a transmitter antenna. The equipment necessary for a specific test is determined by the frequency of the signal to be measured and the accuracy required. Field strength and noise measurements are required to determine antenna efficiency, directivity characteristics, and signal coverage. This information is valuable for selecting antenna sites and for detecting spurious harmonic radiation. Interference, either radiated or conducted, can be detected and located by the use of radio test sets.

The measurement of relative field strength can be made with rather simple test equipment; sometimes a grid-dip meter will suffice. Other test equipment circuits utilize a pickup antenna and a diode (or crystal) detector in connection with a microammeter. In circuits using this combination, the meter reading indicates the relative strength of the field acting on the pickup antenna, and is not directly proportional to the field intensity because of the nonlinearity of the detector.

More elaborate test equipment, for the measurement of absolute field intensity, compares the voltage induced in a pickup antenna with a voltage generated by a self-contained calibrated oscillator. The antenna is connected to a sensitive receiver, which usually incorporates two calibrated attenuators, one between the antenna and mixer stage, and the other in the first IF amplifier stage. A meter in the test equipment measures the diode current in the second detector and indicates the field intensity, usually in terms of microvolts per meter.

In (A) of figure 8-13, a schematic of a simple type of crystal detector field strength meter is shown. The crystal detector is mounted in the center of a pickup antenna, whose length ideally is one-half wave at the frequency of the received signal. The crystal is coupled to a 0-1 milliammeter through radio frequency choke coils. The induced signal is rectified by the crystal, and the resulting current is indicated on the milliammeter. This type of meter is used at distances of four or five wave lengths from the transmitting antenna and for low power transmitter measurements.

In (B) of figure 8-13, a schematic of a considerably more sensitive field strength meter is shown. Tube V1 is an RF amplifier, the output of which is impedance coupled to the diode section of V2, a detector amplifier. The rectified signal voltage is developed across R1, one end of which is attached to the filament-cathode of the amplifier tube. The voltage developed across R1 controls the plate current of V2 which is read on the milliammeter in the plate lead. The amount of change in the plate current is an indication of the strength of the signal induced in the pickup antenna of the field strength meter.

Lettering Lesson 4

OBJECTIVE: To study the form and shape of proper lettering and the method of achieving good results.

RELATED INFORMATION:

A beginner in the field of drafting seldom realizes the importance of good lettering until he becomes an applicant for a position. Employers are very conscious of this and keep a wary eye in that direction. It is thus obvious that the student needs to practice lettering seriously and often, for without the ability to letter properly, obtaining initial employment becomes more difficult.

Vertical lettering rather than slanted is used more commonly in industry; we shall therefore concentrate on this form of lettering.

It is virtually impossible to do consistently good lettering without the use of guide lines, and almost all draftsmen use them. These are drawn lightly with a hard pencil (preferably 6H). Always use upper case capital letters when lettering. Practice diligently, for there is no short approach to becoming a good letterer. Fig. 1 shows correctly how to letter, along with the proper usage of guide lines. The correct height to letter is approximately $\frac{1}{8}''$, but for practical purposes, $\frac{1}{2}''$ lettering is easier.

FIG. 1

1331 0861

Tube V2 is a variable mu pentode. In this type of amplifier, large signal voltages are amplified by a relatively small amount, and small signal voltages receive much greater amplification. The e_c-i_b curve of such a tube is essentially a logarithmic curve. As a result of this fact, the meter in vacuum tube field strength circuits of this type can be calibrated directly in decibels, a logarithmic unit of power or voltage level.

When using field strength meters, errors and erratic readings can be caused by the presence of objects or persons near either the radiating source or the test meter, resulting in shadows and reflections in the radiated field.

The antenna of the test meter should always be extended to its full length so as to keep its effect on the tuning circuit constant.

Many types of field strength indicators are intended for use within 25 feet of the equipment being tested when antenna adjustments are made to achieve maximum radiation. The distance which results in the most satisfactory operation of the instrument for this test varies with the type of equipment being tested. Usually it is desirable to select a distance for the measurements which give a meter reading at about half-scale.

Standing Waves

It is often desirable to determine how much of the generated RF power is actually radiated from the antenna, or more specifically, to check the transmission line for losses. This test is made by using a standing wave ratio meter. There are different types of standing wave ratio meters. All are similar in that they indicate the amount of power produced by the transmitter as compared to the amount of power reflected from the antenna back to the transmitter. The MM-706 is a typical standing wave ratio meter.

The MM-706 is a small portable instrument that may be employed to read directly the RF power output of a transmitter; incident power, reflected power, and net power delivered to a load; and the voltage standing wave ratio (VSWR) of the associated transmission line. It also provides a means of monitoring the modulation on an AM carrier.

This instrument may also be used as an absorption type wattmeter by employing an appropriate dummy load resistor adapter supplied for that purpose.

The unit may be installed permanently in a transmitting system to provide continuous indications, or it may be used only during tuning and test procedures. The output of the transmitter under test is attached to one end of the coupler unit, and the load (or antenna) is connected to the other end.

The coupler unit has negligible effect on the operation of the transmitter or the load. A sample of the RF energy passing through the coupler is applied to the indication circuit of the instrument. The RF energy is rectified by a series crystal unit and applied to the indicator meter.

The particular function of the instrument is selected by means of a switch on the front panel. If remote indication is desired (a remote meter, or headphones), the lead to the remote indicator is connected through the jack on the front panel. When a remote indicator is used, the circuit to the local meter is opened.

Figure 8-14 is a schematic diagram of the meter. Coupler Z2 is connected in the line between the transmitter and the antenna. RF power passes through this unit. This power is sampled by means of a pickoff in Z2 and coupled through the crystal unit CR2 to P2. The prop-

AT.101

Figure 8-14.—MM-706 VSWR meter, schematic.

erties of CR2 are such that in the direction indicated by the arrowhead in figure 8-14 the resistance is low; whereas in the opposite direction, the resistance is very high and conduction is practically negligible.

When S1 is in the FOR position, the sampled RF power is rectified by CR2 and applied through the two sections of the switch, resistor R2, and the normally closed contacts of J1 to the meter.

Filtering of the rectified voltage is obtained by means of a capacitor built into the cap which secures the crystal units in the plugs.

When S1 is placed in the BACK position, the sampled RF power is taken from the load end of coupler Z2. Rectification occurs in the same manner as previously explained, and meter M1 reads the reflected power.

The standing wave ratio of a transmission line is the ratio of the maximum RF power to minimum RF power. With S1 in the CAL position, the meter is reading forward power or, almost directly, the power output of the transmitter. The circuit to the meter bypasses fixed resistor R2 and includes potentiometer R1. This potentiometer is adjusted to produce full scale deflection of the meter. This is the maximum power.

Placing the selector switch in the VSWR position causes the RF power at the load end of the coupler unit to be sampled. At this point the reflected power from the antenna back toward the transmitter is bucking the forward power. Therefore, the load end is a low power point. Since the meter was set for full scale deflection at the maximum power point, the reading obtained from the low power point is a direct indication of the voltage standing wave ratio.

FREQUENCY MEASUREMENT

Frequency measurements are often an essential part of preventive and corrective maintenance for electronic equipment. Rotation frequencies of some mechanical devices must be determined. The output frequency of electric power generators is checked when the engine is started and during preventive maintenance routines. Equipment which operates in the audiofrequency range must be adjusted to operate at the correct frequencies. Radio transmitters must be accurately tuned to the assigned frequencies to provide reliable communications and avoid interfering with radio circuits operating on other frequencies. Radar sets must be properly tuned to obtain satisfactory performance.

The rotation frequency of rotating machinery such as radar antennas, servomotors, and other types of electric motors can be measured by the use of a stroboscope. Stroboscopic methods compare the rate of one mechanical rotation or vibration with another or with the frequency of a fluctuating source of illumination. Tachometers can be used to measure the rotation frequency of armatures in electric motors, dynamotors, and engine-driven generators.

The electrical output frequency of a-c power generators can be measured directly by vibrating reed, tuned circuit, or crossed-coil iron-vane type meters. The vibrating reed device is the simplest type of frequency meter, and has the advantage of being rugged enough to be mounted on generator control panels. It is also used to check the line voltage in the shop to insure that the proper frequency is supplied to the equipment and/or test sets.

Frequency Meters

"Frequency meter" is a term generally applied to denote an item of test equipment which is used to indicate the frequency of an external signal. Although some models of frequency meters generate signals having a basic frequency, they should not be confused with that class of test equipment known as signal generators. (Signal generators are discussed later in this chapter.) The signal generator develops a frequency used to operate an external circuit; the frequency meter measures the frequency of a signal developed in an external circuit.

As mentioned previously, some frequency meters generate a signal frequency; others do not. The group in which no frequency is generated internally is properly called a "wavemeter." Wavemeters are of two basic types—reaction and absorption. Those frequency meters which do generate an internal frequency may use either electronic or mechanical oscillation as the frequency generator.

Measurement Methods

Frequency measurements in the audio-frequency range can be made by the comparison method or by a direct-reading frequency meter. Frequency comparisons can be made by the use of a calibrated audiofrequency signal generator in conjunction with either an oscilloscope or a modulator and a zero-beat indicator device. Direct-reading frequency measurements can be made by instruments using series frequency-selective electrical networks, bridge test sets having null indicators, or counting type frequency meters.

Frequency measurements for radio equipment are made during tuning, preventive maintenance, and corrective maintenance procedures. The type of test equipment selected depends on the frequency to be measured and the required accuracy. Signal frequencies of radio transmitters which operate in the low frequency to the VHF range are normally measured by absorption type wavemeters, reaction type wavemeters, heterodyne type frequency meters, or calibrated radio receivers. Where accuracy is not of prime importance, rapid frequency checks may be made by the absorption type wavemeter. Since the wavemeter is relatively insensitive, it is very useful in determining the fundamental frequency in a circuit generating multiple harmonics. Calibration of test equipment measure signals in this frequency range can be checked by comparison with standard frequency signals broadcast by the National Bureau of Standards.

The signal frequencies of radio and radar equipment which operate in the UHF and SHF range can be measured by resonant cavity type wavemeters, resonant coaxial line type wavemeters, or Lecher-wire devices. When properly calibrated, resonant cavity and resonant coaxial line wavemeters are more accurate and have better stability than wavemeters used for measurements in the low frequency to VHF range. These frequency-measuring instruments are often furnished as part of communication and electronic equipment, but are also available as general purpose test sets.

Heterodyne Type Meters

Heterodyne type frequency meters are available in several varieties. Although they all function in the same general manner, some differences exist in the manner of accomplishing their purpose.

Test instruments of this class generate a signal within the test set. This signal is mixed with a signal from the equipment under test to obtain a beat frequency. The frequency of one signal is then changed to obtain a zero beat. (The beat frequency is the difference frequency which results from heterodyning two signals. A zero beat is obtained when heterodyning two signals of the same frequency.) The frequency of the unit under test may be determined by reading the frequency indicator of the test set.

A heterodyne type frequency meter usually consists of a heterodyne oscillator, an RF harmonic amplifier, a crystal-controlled oscillator, a mixer or detector, a modulator, an AF output amplifier, and a means for indicating frequency. (See fig. 8-15.) Most models are furnished with a set of calibration charts giving the dial readings for the frequencies listed, together with a table of the crystal harmonics; thus a complete and accurate frequency coverage over the designed range is provided. Some models indicate the frequency directly on dials.

The crystal-controlled oscillator operates at a fixed frequency, but is also capable of emitting various harmonic frequencies of the crystal for use as check frequencies. These checkpoints are then used for adjusting the heterodyne oscillator, thus insuring more accurate operation. Provisions are usually made within the crystal-controlled oscillator for precise adjustment to its assigned fundamental frequency.

The TS-186D/UP test instrument is a general purpose, crystal-controlled, heterodyne

AT.102

Figure 8-15.–Crystal-calibrated heterodyne frequency meter, block diagram.

13343

type frequency meter used to measure the frequency of transmitters, oscillators, or signal generators. It provides both visual and aural indications of signal frequency by means of a beat indicating meter, headphones, and a video output jack for observation on an oscilloscope, as desired. A vernier tuning dial and an associated calibration chart are used in making frequency measurement determinations. The instrument is usable for either field or depot level maintenance testing.

The RF input is routed through waveguide and coaxial cable to a detector mixer, where it is mixed with the output of a heterodyne oscillator. From these inputs, the difference signal is then routed through an audio amplifier. A crystal oscillator, when substituted for the input signal, is used to check the frequency calibration of the heterodyne oscillator. This checking is done at specified checkpoints near the frequency at which the frequency measurement is to be made.

A d-c milliammeter is included for the following functions:

1. Help to indicate a zero beat.
2. Measure the grid current of the crystal oscillator when used.
3. Measure the cathode current of the detector mixer.
4. Measure the cathode current of the heterodyne oscillator.
5. Measure the cathode current of the various indicators.

A selector switch determines which value is to be measured. The indicator circuit causes a dip in meter reading near the zero-beat indication. The meter, however, does not respond to frequencies less than 100 Hz; therefore, a pair of headphones is used to provide more accurate indications of zero beat. The video output is obtained through a jack in the output of the detector mixer circuit.

The instrument is usable for CW, MCW, or pulsed signals in the frequency range of 100 to 10,000 MHz, with signal input magnitudes of 500 μ v to 1 v. The bandpass of the audio amplifier is 100 kHz, to 100 kHz; audio output impedance is 600 ohms. For airborne use, the equipment is usable up to altitudes of 10,000 feet without requiring additional pressurization.

Wavemeters

Wavemeters are calibrated resonant circuits used to measure frequency. Although the accuracy of wavemeters is not as high as that of heterodyne frequency meters, they have the advantage of being comparatively simple and can be easily carried about.

Any type of resonant circuit may be used in wavemeter applications. The exact kind of circuit employed depends on the frequency range for which the meter is intended. Resonant circuits consisting of coils and capacitors are used for low frequency wavemeters. Butterfly circuits, adjustable transmission line sections, and resonant cavities are used in VHF and microwave instruments.

There are three basic kinds of wavemeters—the absorption, the reaction, and the transmission types.

Absorption wavemeters are composed of the basic resonant circuit, a rectifier, and a meter for indicating the amount of current induced into the wavemeter. In use, this type of wavemeter is loosely coupled to the circuit to be measured. The resonant circuit of the wavemeter is then adjusted until the current meter shows a maximum deflection. The frequency of the circuit under test is then determined from the calibrated dial of the wavemeter.

The reaction type derives its name from the fact that it is adjusted until a marked reaction occurs in the circuit being measured. For example, the wavemeter is loosely coupled to the grid circuit of an oscillator, and the resonant circuit of the meter is adjusted until it is in resonance with the oscillator frequency.

The setting of the wavemeter dial is made by observing the grid current meter in the oscillator. At resonance, the wavemeter circuit takes energy from the oscillator, causing the grid current to dip sharply. The frequency of the oscillator is then determined from the calibrated dial of the wavemeter.

This type is commonly referred to as a "grid-dip" meter, and is discussed in Basic Electronics.

The transmission wavemeter is an adjustable coupling link. When it is inserted between a source of radiofrequency energy and an in-

13344

13344

dicator, energy is transmitted to the indicator only when the wavemeter is tuned to the frequency of the source. Transmission wavemeters are widely used in measuring microwave frequencies. Units of this type are included in echo boxes. The additional provisions for echo boxes permit additional testing functions.

Many actual wavemeters are used in performing various functions. Cavity type wavemeters are the type most commonly used, and only this type is discussed in detail.

Cavity Wavemeters

Figure 8-16 shows a typical cavity wavemeter. The wavemeter illustrated is of the type commonly used for the measurement of microwave frequencies. The device employs a resonant cavity which effectively acts as a high-Q, LC tank circuit. The resonant frequency of the cavity is varied by means of a plunger which is mechanically connected to a micrometer mechanism. Movement of the plunger into the cavity reduces the cavity size and increases the resonant frequency. Conversely, an increase in the size of the cavity (made by withdrawing the plunger) lowers the resonant frequency. The microwave energy from the equipment under test is fed into the wavemeter through one of two inputs, A or D. A crystal rectifier then detects (rectifies) the signal, and the rectified current is indicated on the current meter, M.

AT.103

Figure 8-16.—Typical cavity wavemeter.

This specific instrument can be used as either a transmission type or an absorption type wavemeter. When used as a transmission wavemeter, the unknown signal is coupled into the circuit by means of input A. When the cavity is tuned to the resonant frequency of the signal, energy is coupled through coupling loop B into the cavity and out through loop C to the crystal rectifier. It is rectified and current flow resulting from this rectification is indicated on the meter. At frequencies off resonance, little or no current flows in the detector and the meter reading is small. The micrometer and attached plunger are varied until a maximum meter reading is obtained. The micrometer setting is then compared with a calibration chart supplied with the wavemeter to determine the unknown frequency.

When the unknown signal is relatively weak, such as the signal from a klystron oscillator, the wavemeter is usually used as an absorption type of device. Connection is made to the instrument at the input D. The RF loop C then acts as an injection loop to the cavity. When the cavity is tuned to the resonant frequency of the klystron, maximum energy is absorbed by the cavity and the meter dips, indicating a reduction of current. When the cavity is not tuned to the frequency of the klystron, high current is indicated on the current meter. Therefore, the cavity is tuned for a minimum reading, or dip, in the meter; and the resonant frequency is determined from the micrometer setting and the calibration chart.

Potentiometer R1 is used to adjust the sensitivity of the meter from the front panel of the instrument. J1 is a video jack and is provided for observing video waveforms with a test oscilloscope.

A directional antenna is used in conjunction with the instrument for making relative field strength measurements of radiated signals, for use in measuring the frequency of radar transmitters, and for constructing radiation patterns of transmitting antennas.

13345

In radiation pattern measurements, the directional antenna is connected to the wavemeter input, and the instrument is tuned to the frequency of the system under test. The cavity is then locked on this frequency by an AFC system. The output signal being measured must be continuous and constant for reliable results. This is necessary in order for any variation in the meter reading to be caused directly by a change in the actual field strength of the signal when the position of the wavemeter is changed with respect to the transmitting antenna. After establishing a reference level on the meter, the position of the wavemeter is then changed by moving it around the radiating antenna, maintaining a fixed distance from it. The wavemeter readings at various positions around the transmitting equipment are recorded on polar graph paper, and the field pattern is thereby determined.

Counting Type

Frequency Meter AN/USM-26 is a precision instrument that automatically measures frequencies to 100 MHz and automatically displays its measurements in digital form on an 8-place panel indicating system. In addition to making direct measurements of frequency, the AN/USM-26 also measures period (time of one cycle of periodic wave), time intervals, and frequency ratios, and may be used to count random events such as those encountered in nuclear work. The equipment further includes a self-check feature that enables the operator to verify the proper operation of the equipment for most types of measurements.

By use of the Frequency Converter AN/USA-5 plug-in unit, the useful operating range of the USM-26 is extended to 220 MHz. Similarly, using the Transfer Oscillator CM-102/USM-73 in conjunction with the USA-5 further extends the frequency range to the vicinity of 5 GHz (gigahertz) before the harmonics become too weak for use. Use of a tunable detector allows the operator to resonate the signal to be measured, thus increasing the sensitivity of the equipment for detection of harmonics. This extends the upper limit of operation to about 12 GHz. A second tunable detector can be used to further increase the sensitivity by resonating the desired harmonic produced by the transfer oscillator.

Because of the accuracy with which it measures frequencies, the USM-26 equipment can be considered to be a new type of secondary frequency standard that replaces more elaborate installations of conventional precision frequency-measuring equipment. For example, the meter has been found particularly useful for frequency measurements in quartz crystal grinding work as well as for general laboratory quality frequency measurements. Other typical frequency-measuring applications for the equipment include calibration of transmitters, oscillators, signal generators, etc.

In combination with tachometer generators or other suitable transducers, the equipment can be used to make precision tachometry measurements. In tachometry work it is particularly useful for measuring the rotation frequency of high speed devices. When used in conjunction with a sensitive radioactivity detector and a suitable transducer, the USM-26 can provide an extremely accurate indication of the radio-activity radiation level.

Time measurements that the equipment will make include pulse length, pulse interval, time delay, etc.

Since the indicating system in the equipment presents the measured frequency in as many as eight significiant figures, the equipment is especially useful for measuring very small frequency changes such as are encountered when making measurements of frequency stability of oscillators and similar frequency generators.

COMPONENT TESTERS

This section discusses the testing of components considered to be most essential in any electronic circuit. These components include the transistor, crystal diode, and the electron tube. During the process of maintaining the equipment for which the technician is responsible, these three particular components are the ones with which he becomes most involved.

ELECTRON TUBE TESTER

Before discussing the testing of electron tubes on the tube tester, the substitution method of testing is described.

13346

Substitution of a tube known to be good is a simple and reliable method of determining the quality of a questionable tube. Usually this method cannot be used to eliminate more than one tube in a single circuit. For instance, if both an RF amplifier and an IF amplifier are defective in a receiver, replacing either one does not correct the trouble. Also the practice of replacing several tubes in a circuit, all at one time, will usually result in misalinement of a tuned circuit. Under conditions such as these, the use of test equipment designed for testing the quality of a tube saves valuable time.

Experience has shown that tube failures may be roughly classified as follows: mechanical defects and gas within the tube, filament (or heater) burned out, change in tube characteristics, physical damage, and intermittent shorts. Mechanical defects and rise of gas pressure within the tubes are attributed to faulty construction and processing. Some of these defects cannot be detected by standard testing methods until the tubes have been in operation for some time. Filament burnout may be caused by repeated sudden application of full voltage to the filament. Initial heating of the filament is nonuniform. As a result, mechanical stresses due to thermal expansion are set up, and these stresses weaken the filament structure and hasten its failure.

Change in tube characteristics is a broad classification and covers decreasing emission, change in cutoff voltage, changing transconductance, etc. Such changes are usually the result of deterioration of the cathode structure, or formation of a cathode interface surface in the tube or changes in alinement of the electrode parts. Physical damage is largely accidental. It includes such causes as breakage, bending of pins, and inadvertent application of excessive voltages. Intermittent shorts are caused mainly by foreign matter, such as lint within the tube assembly.

Two common types of tube-testing equipment are the emission tube tester and the transconductance tube tester. These types may also incorporate circuits for making important tests other than emission and transconductance. Several types of tests are described in the following paragraphs.

Emission Tube Tester

The emission tester measures the condition of the cathode emitting surface. The end of the useful life of a tube is usually preceded by a reduction in electron emissivity, that is, the cathode becomes unable to supply the number of electrons necessary for proper tube operation. Also, if the tube has an open element, the defect prevents proper emission, and the tester indicates it as a reject. Both multigrid and diode tubes are tested for cathode emission.

The emission tester has certain limitations and disadvantages. Since the manufacturer of a tube does not state a definite 100 percent emission point which could be used for reference, the emission test is not conclusive. High emission does not necessarily indicate a good tube, because this condition might be present in a tube with a faulty grid structure or one which has a highly emissive spot on its cathode. Very high emission has also been observed just before a tube fails completely; hence, fairly low emission does not necessarily indicate in all cases that a tube is near its end-of-life point.

A further disadvantage of the emission test is that gas is liberated within the tube when a-c test voltages are applied unless the test is made quickly. Also, because the tube is not tested with its circuit d-c electrode voltages in this test, it is not tested under actual operating conditions. It is also possible for a tube to show normal emission and still not operate properly. The reason for this is that the efficiency of a tube depends on the ability of the grid voltage to control the plate current. The emission type tester tests only the plate current developed, and not the ability of the grid to control the plate current. The transconductance type tester checks the latter characteristic.

Transconductance Tube Tester

The term transconductance (also called mutual conductance) expresses the effect of grid voltage upon the plate current of a tube. By measuring the transconductance of a tube it is possible to evaluate the condition of the tube much more accurately than by measuring its cathode emission, because this test more closely approximates actual circuit conditions.

13347

13346

Transconductance is expressed mathematically as the ratio of a change in plate current to a change (small) in control-grid voltage with all other electrode voltages held constant. Transconductance is measured in units of conductance called micromhos. The equation for transconductance is:

$$G_m = \frac{\Delta I_p}{\Delta E_g}$$

where G_m is the transconductance in micromhos, ΔIp is the change in plate current in microamperes, and ΔEg is the change in control-grid voltage. When the control-grid voltage changes 1 volt (positive or negative), the current change in microamperes is equal to the transconductance in micromhos. In other words, if an amplifier tube has a transconductance of 2,000 micromhos, a 1-volt change in the control-grid voltage will cause a plate-current change of 2,000 microamperes. The transconductance of a tube may be measured by two methods: one method is the static (d.c.) method and the other is the dynamic (a.c.) method.

STATIC METHOD.–In the static method (also called the "grid shift" method) of measuring transconductance, the d-c bias voltage on the control-grid of the tube under test is changed, and the resultant change in the steady plate current is measured with a current meter. The test circuit is shown in (A) of figure 8-17.

With switch S set to position 1, a negative bias voltage is applied to the control grid of the tube and causes a certain value of plate current to flow. When switch S is set to position 2, the control-grid voltage becomes less negative, and the plate current increases to a new value. If the control-grid voltage is varied by 1 volt, the transconductance is the difference (in microamperes) between the initial plate current reading and the new value of plate current. When such a circuit is used to test various types of tubes, the voltage applied to the electrodes must be made adjustable, so that the correct operating conditions for each tube type may be attained.

DYNAMIC METHOD.—The dynamic method of determining transconductance makes use of a circuit which applies an a-c signal to the

AT.104

Figure 8-17.—Basic circuits used for transconductance test.

control grid of the tube under test, in addition to a fixed (operating) control-grid bias. The basic circuit is shown in (B) of figure 8-17. The tube under test serves as the load for the rectifier circuit. The d-c milliameter is connected across a center-tapped resistor, the upper and lower parts of which are designated as R1 and R2. The meter and resistor combination is placed in series with two secondary windings of the a-c line-voltage transformer. With a fixed value of bias voltage (E_g) applied to the control grid of the tube under test, the circuit operates as a simple full-wave rectifier.

On the half-cycle of the a-c voltage when plate P1 of the double diode is positive, there is a current flow through R1, and the force exerted on the meter pointer attempts to deflect it in one direction. When the a-c voltage reverses and plate P2 is positive, the current flows through R2, and the force exerted on the meter pointer is equal and opposite to the pre-

vious force. Since these alternations occur at a rather rapid rate (60-hertz line voltage), the resultant force exerted on the meter pointer is zero; consequently, it remains stationary in the zero position.

Operation of a Typical Tube Tester

The tube-testing equipment discussed in this section is a typical, general-purpose test equipment of the transconductance type. The TV-7/U tube tester (fig. 8-18) is representative of this type equipment.

The front-panel controls on this tester adjust (or switch) the various potentials necessary for the testing of tubes. The tube data chart (booktype) which is supplied with the equipment, lists the control setting for the various types of tubes generally encountered in the field.

CAUTION: Before the tube to be tested is inserted in the correct test socket, make certain that the front-panel controls are set to the positions listed for that type tube in the data chart. This precaution is necessary to prevent excessive voltage from being applied to the tube elements (especially the filament).

LINE VOLTAGE ADJUSTMENT AND TEST.–The line voltage adjustment is necessary so that the line voltage applied to the primary of the transformer can be preset to an operating value. A 93-volt potential is used as a test reference point, regardless of the variations caused by different tube loads or fluctuations in the a-c supply. Applied voltages may range from 105 to 130 volts and still be adjustable. Depressing the LINE TEST button connects the meter of the tube tester to read the "B" supply voltage. The test equipment is calibrated at the factory so that the meter pointer is approximately centered when the voltage across the primary is 93 volts. Since various types of electron tubes draw different values of currents, a LINE ADJUSTMENT rheostat (connected in series with the primary) is provided. The primary voltage can thus be set to the designed operating voltage before any test is begun. A small protective lamp which will burn out on overload is connected in series with the primary of the transformer to prevent equipment damage.

SHORT CURCUIT AND NOISE TEST.–It is very important that the technician apply the test for short-circuited elements to a tube of doubtful quality before any other tests are made. This procedure protects the meter (or any other indicator) from damage. Also it follows logically that, if a tube under test has elements which are short-circuited, there is no further need to apply additional tests to that tube. Short-circuit tests are usually sensitive enough to indicate leakage resistance less than about one-fourth megohm. The proper heater voltage

ASSIGNMENT:

On the 17" x 22" buff paper issued to you, draw a horizontal line $1\frac{1}{4}$ inches from the bottom border. This space can be used for the title block, which includes the name of the school, student's name, etc. Lay out two $8\frac{1}{2}$" x 11" lettering blocks so that the spaces between the blocks and the margin are equal. Draw the $\frac{1}{2}$-inch border inside the blocks as shown in Fig. 2.

When all the guide lines are drawn, place a piece of tracing paper over the drawing sheet and proceed to practice, freehand, the letter strokes as shown in Fig. 2. Use a soft pencil.

1332

is applied so that any tube elements which might short as a result of the heating process will be detected. The short-circuit test is similar to the test used to detect noisy (microphonic) tubes caused by loose elements. Since the only difference between the two tests is in the sensitivity of the device used as an indicator, the noise test is discussed as part of the short-circuit test.

Figure 8-19 shows a basic circuit used for detecting shorted elements within a tube. With the switch set to position 2 as shown, the plate of the tube under test is connected to the leg of the transformer secondary containing the neon lamp. All the other elements are connected through switches to the other leg of the secondary. If the plate element of the tube is touching any other element within the tube, the a-c circuit of the secondary is completed and as a result, both plates of the neon lamp glow. If no short exists, only one plate of the neon lamp will glow. Each of the other elements is tested by means of the switching arrangement shown. Resistor R2 limits the current through the neon lamp to a safe value. Resistor R1 bypasses any small alternating currents in the circuit which might be caused by stray capacitance and thus prevents the neon lamp from indicating erroneously. Tapping the tube lightly is recommended to detect loose elements which might touch when the tube is vibrated.

In the test set shown in figure 8-18 the circuit used to test for shorts is similar to the basic circuit of figure 8-19. By means of the function switch the electrodes of the tube under test are switched in turn across a neon SHORTS lamp, which is connected in series with the secondary of the transformer. Shorted tube elements (and any other internal tube connections) complete the a-c circuit, causing both plates of the neon lamp to glow. Momentary flashes of the neon SHORTS lamp may be caused when the switch is rotated. These flashes are caused by the charging of the small inter-electrode capacitances of the tube when the voltage is applied, and do not indicate short circuits. If the tube under test has a shorted element, the neon lamp will glow continually on one or more switch positions. Since the filament circuit and other internal tube connections will show up as short circuits in this test, the tube data chart should be consulted for pin connection information before interpreting the results of the test.

The noise test is used to check for intermittent shorts or microphonic noise. The circuit used is the same as that employed for the short-circuit test. In tests for noise, the antenna and ground terminals of a radio receiver are connected to the NOISE TEST receptacles. Any intermittent short between tube electrodes permits the a-c voltage from the power transformer to be applied momentarily to the neon lamp.

The brief oscillation of this lamp contains various radiofrequencies which are reproduced as audible signals in the receiver speaker. A less sensitive noise test can be made using a pair of headphones instead of the radio receiver. The tube should be tapped while it is being tested.

AT.106

Figure 8-19.–Basic circuit used for short circuit and noise tests.

13351 DECL.

GAS TEST.–In all electron tubes, except some types of rectifier tubes and thyratrons, the presence of any appreciable amount of gas is extremely undesirable. When gas is present, the electrons emitted by the cathode collide with the molecules of gas. As a result of these collisions, electrons (secondarily emitted) are dislodged from the gas molecules, and positive gas ions are formed. These ions are attracted by (and cluster around) the control grid of the tube, because it is negative (bias) and absorbs electrons from the grid circuit in order to revert to the more stable gas molecules (not ionized). If the amount of gas in the tube is appreciable, the collisions between the numerous gas molecules and the cathode-emitted electrons release many secondarily emitted electrons, and the resulting flow of grid current is high.

The basic circuit used for the gas test is shown in figure 8-20. With switch S set to position 1, a certain value of plate current is measured by the d-c milliammeter. If there is no gas (or a negligible amount) present in the tube, setting switch S to position 2 does not change the plate-current reading. If gas is present, current flows through the grid resistor (large value), causing a voltage drop to develop with the polarity as shown. The net effect is to reduce the negative bias voltage on the grid of the tube resulting in an increase of plate current. Small plate current increases are normal; large increases indicate excessive gas.

AT.107

Figure 8-20.–Basic circuit used for gas test.

The value of the grid resistor used in the typical tube tester is 180,000 ohms. Two push-button switches, labeled GAS No. 1 and GAS No. 2, are used for gas test. GAS No. 1 button is first depressed and the plate current reading on the meter is noted. Depressing the button marked GAS No. 2 inserts the 180,000-ohm resistor into the grid circuit. If gas is present in the tube, the grid current that flows reduces the normal bias on the tube and increases the plate current measured by the meter. A tube with a negligible amount of gas produces an increase in plate current of less than one scale division when GAS No. 2 button is depressed. An increase of more than one scale division indicates an excessive amount of gas in the tube.

CATHODE LEAKAGE TEST.–The cathode element of an electron tube is essential because it supplies the electrons necessary for tube operation. Electrons are released from the cathode by means of some form of energy–generally heat–which is applied to it. An indirectly heated cathode consists of a heater wire (usually a tungsten alloy) enclosed in, but insulated from, a metal sleeve (nickel). This sleeve is coated with an electron emitting material (usually strontium or barium compounds) on its outer surface, and is heated by radiation and conduction from the heater. Useful emission does not take place from the heater wire.

When a tube which uses an indirectly heated cathode develops noise, it is almost a certain indication that a leakage path is present between the cathode sleeve and the heater wire. This assumption is justified because in the design of a tube the heater must be placed as close as possible to the cathode so that maximum tube efficiency is attained. Continual heating and cooling of the tube structure may cause small amounts of the insulation between the cathode and heater to become brittle or deteriorate, leaving a high resistance leakage path between these elements. Under extreme conditions the insulation may shift enough to allow actual contact of the elements. Since the heater and cathode are seldom at the same potential, any form of leakage causes noise to develop in the tube.

The cathode normally is maintained at a higher positive potential, because cathode bias

13352

is the most common type of bias utilized. The heater circuit is usually grounded to chassis, either on one side of the filament supply or by a center-tap arrangement. Therefore, if a resistance path is present, a leakage current may flow from the heater to the cathode. Thus, in effect the cathode functions in the same manner as the plate of a tube; that is, it receives electrons. Assuming the existence of a high-resistance short, the current flow from the heater to the cathode will vary with any vibration of the tube because vibration varies the amount of resistance. If the cathode and heater are completely shorted (zero ohms), it is impossible for the tube to develop any cathode bias.

A cathode leakage test is sometimes made while a tube is being tested for short-circuited elements or noise. However, some tube-testing instruments incorporate the cathode leakage test as an additional test which is not part of the short-circuit test. Figure 8-21 shows a basic circuit which is used to detect leakage between the heater and cathode elements of a tube. With switch S set to position 2, a certain value of plate current flows.

When switch S is set to position 1, the cathode becomes a floating element; if no leakage path is present, the plate current should fall to zero. If the elements are completely shorted, the plate current reading remains the same as the initial reading (switch S in position 2); if they are only partially shorted, a plate current less than normal but greater than zero is indicated.

FILAMENT ACTIVITY TEST.–The filament activity test is used to determine the approximate remaining life of an electron tube insofar as the longevity of the cathode emitter is concerned. The test is based on the principle that the cathode in almost all electron tubes is so constructed that a decrease of 10 percent of the rated heater voltage causes no appreciable decrease in emission.

On a tube-testing equipment incorporating this test there is a two-position switch (FILAMENT ACTIVITY TEST) which has one position marked NORMAL and the other marked TEST. The switch remains in the NORMAL position for all tests other than the filament activity test. When the switch is set to the TEST position, the filament (or heater) voltage which is applied to the tube under test is reduced by 10 percent.

The filament activity test is performed as follows: After the quality test is made, the TUBE TEST button is held depressed, and the filament activity test switch is set to TEST position. If the indicator shows a decreased reading after a reasonable time is allowed for the cathode to cool, the useful life of the tube is nearing its end.

RECTIFIER TEST.–The circuit used for testing full-wave rectifiers, diodes, and 0Z4 tubes is an emission test circuit which is similar to the basic circuit shown in figure 8-22. An a-c voltage of definite value is applied to the tube under test, and the meter indicates the rectified plate current. The two sections of a full-wave rectifier are tested separately.

AT.108

Figure 8-21.–Basic circuit used for cathode leakage test.

AT.109

Figure 8-22.–Basic circuit used for emission test.

13353

The button for testing OZ4 cold-cathode rectifier tubes provides a higher a-c voltage than is normally used for heater (or filament) type rectifiers. The button for diode tubes provides a lower voltage than that used for regular rectifiers, and also inserts a protective series resistance.

QUALITY TEST.–For the quality test, the d-c grid bias for the tube under test is supplied by a rectifier tube. The correct value of this grid bias is obtained when the bias control is rotated to the setting listed in the test data chart, for the tube being tested. An a-c voltage (4.7 volts rms), which is taken from a separate winding on the power transformer, is applied in series with the grid bias. This voltage causes the grid to deviate in positive and negative directions from the d-c bias level, thereby effecting the grid-voltage change (ΔE_g) required for a dynamic transconductance test. The plate voltage of the tube under test is supplied by a rectifier tube. The meter which indicates the plate current change (ΔI_p) is in the return circuit of the rectifier supply. The meter indicates the tube condition in arbitrary numerical units from 0 to 120. The tube test data book, mounted inside the cover of the equipment, lists the minimum numerical value of meter reading for satisfactory performance. Tubes reading below this value are not considered suitable for use in military equipment. The shunt control is used to control the sensitivity of the meter. Setting of the dial is required only when the function switch is in the RANGE (A) SHUNT position. The setting for this switch is determined by the type of tube being tested and is listed in the tube data chart. The operation of this circuit is the same as that of the basic circuit shown in part (B) of figure 8-17.

SEMICONDUCTOR TESTERS

Since semiconductors have replaced vacuum tubes in many new equipments, the testing of semiconductors has become increasingly vital. Two basic types of equipment are discussed in this section. They are the crystal diode tester and the in-circuit transistor tester, represented by the TS-1100/U.

Microwave Crystal Test Set

Microwave Crystal Test Set, Type 390 is used to provide an accurate and reliable indication of the quality of mixer crystals. Its accuracy is comparable to that of more elaborate laboratory test setups, but its testing versatility is more limited.

The quality of a microwave crystal can be determined by measurement of its conversion loss and noise temperature. The Type 390 is designed specifically to perform these tests on crystals intended for use at frequencies of 10,000 MHz and lower. For crystals used at frequencies above that figure, the readings are relative—crystals can still be selected in the order to comparative quality.

Conversion loss is defined as the ratio of the power available from the RF signal source to the power available at the IF output of the mixer. Noise temperature is defined as the ratio of the IF noise power available from the crystal to the thermal noise power available from a resistance (equal to the RF resistance of the crystal) at room temperature. The theory of the mixer crystal test set is based on the fact that the minimum conversion loss and noise temperature can be determined from the degree of nonlinearity of the static voltage-current (E-I) curve of a mixer crystal.

The Type 390 measures this nonlinearity by measuring the incremental change in crystal current (Δi) caused by an incremental change in voltage (Δe) applied to the crystal in the "forward" direction. Adjustment is made to the variable resistor R101 with the CAL-TEST switch in the CAL position. (See fig. 8-23.) If the E-I curve of the crystal under test were linear, a midscale reading would be obtained on meter M101 when S101 was switched to the TEST position. If the reading actually obtained is below midscale, the E-I curve of the crystal is nonlinear. The amount by which the reading falls below the midscale point is a measure of the degree of crystal's nonlinearity. The lower the meter reading below midscale, the more nonlinear the E-I curve for that crystal, and the lower its conversion loss and noise temperature.

Figure 8-23 is a schematic diagram of the test set. The initial adjustment of voltage V_i is made using variable resistor R101 with the

13354

AT.110

Figure 8-23.–Microwave Crystal Test Set, Type 390, schematic diagram.

CAL-TEST switch S101 in the CAL position. (An incorrect adjustment of R101 may apply excessive voltage to M101, causing damage to the pointer. For this reason, R101 should always be set fully clockwise before switching to the CAL position). Also, see figure 8-24.

Fixed resistors R102, R104, R105, and R106 determine the limits to which V_i can be adjusted. The voltage increment (Δe) is established by R103 and R107 when in the TEST position; it has the same value for all crystals.

When a crystal is to be tested, it is placed in crystal holder X101. The crystal should always be handled by the base; while inserting the crystal, any static charge should be removed by touching the base to the grounding spring on the holder. The switch is set to the CAL position, and R101 is adjusted until the meter indication coincides with the calibration scale reading of R101. When S101 is moved to the TEST position, M101 indicates the quality of the crystal. With the aid of a chart supplied with the test set, the reading of M101 can be

AT.111

Figure 8-24.–Type 390 microwave crystal checker.

13355

converted to the actual conversion loss and noise temperature. Block sections on the meter scale help ease the acceptance or rejection of crystals according to the type being tested.

The purpose of the NORM/REV switch (S-102) is to provide the correct bias-voltage polarity for the crystal diode being tested; and to determine the polarity of a crystal diode when it is not known or when the crystal diode is located remotely from the test set.

In-Circuit Transistor Checkers

Test Set, Transistor TS-1100/U (fig. 8-25) is designed to measure the beta parameter of a transistor when the transistor is connected in a circuit, and to measure beta and I_{co} parameters with the transistor removed from the circuit.

AT.112

Figure 8-25.–Test Set, Transistor TS-1100/U.

The characteristics of the test set are:

1. Range of beta 10 to ∞ in a single band.
2. Leakage current measurements: 0° to 50 microamperes.
3. Temperature range: 0° C to +50 C.
4. Power Supply: Battery operated.

The equipment contains two separate battery power supplies. One provides the power for the internal circuits, and the other furnishes the bias voltage required for the transistor under test. Either the mercury type of zinc-carbon batteries may be used for operation of the test set.

Low impedance techniques are used for measurement to isolate the transistor under test from the surrounding circuitry. The measurement accuracy of the tester is within ±20 percent provided that the loading of the emitter-base diode or the collector-base diode is not below 500 ohms, and the loading between the collector and the emitter is not below 500 ohms. If the emitter-base load contains a diode, the series impedance should not fall below 7,000 ohms to maintain this accuracy.

With the use of an appropriate shorting technique, the accuracy can be improved. The shorting technique consists of connecting a jumper wire between the emitter of the transistor under test and the far side of all components connected to the base electrode of the transistor. This technique is not universally applicable, and it should be employed only by skilled personnel.

The range of beta that can be measured is between 10 and ∞. A beta of infinity (∞) corresponds to zero microamperes on the readout meter scale. A transistor having a beta below 10 will cause the pointer of the meter on the tester to move off the scale. Because of the nonlinear characteristic of the meter scale, which causes crowding at the high end, the readout accuracy for betas above 100 is impaired.

The following controls, as seen on the front panel (fig. 8-25), are incorporated in the test set:

1. POWER switch (labeled ON-OFF): Turns the internal power source on or off.
2. PNP-NPN (transistor select) switch: Selects proper collector bias polarity for the type transistor under test.
3. BETA switch: Permits readout of beta.
4. BIAS SELECT switch: Used to set proper collector bias voltages (nominally 3, 6, or 12

13356

volts). Also checks the condition of internal battery when in the TEST position.

5. RED LINE SET control: Adjusts the amplitude of the test signal.

6. SHORT switch (labeled CB, CE, BE): Enables measurement of a short circuit or a low impedance in the collector-base (CB), collector-emitter (CE), or base-emitter (BE) circuits.

7. I_{CO} switch: Enables readout of transistor leakage.

8. SHORT indicator: The indicator lamp will light when a short circuit or low impedance exists in either the transistor under test or in the surrounding circuitry. If the lamp lights, this indicates a load of less than 500 ohms.

9. TEMPERATURE indicator: The indicator lamp will light when the ambient temperature surrounding the equipment exceeds +50° C. This indicates that the equipment is operating in an environment beyond that for which it has been designed, and that measurement inaccuracies will arise.

10. METER: Indicates magnitude of beta; indicates magnitude of I_{CO}; and indicates the condition of the internal battery. (The battery is good when the meter needle moves under the green band on the dial.)

11. PROBE connector: For connecting the cables (furnished with the test set) to the transistor to be tested.

12. TRANSISTOR socket (labeled E-B-C): Enables direct connection between the test set and transistor to be tested.

13. BATTERY DISCONNECT switch (upper left corner of panel–not labeled): Disconnects the internal battery when the front cover is snapped in place.

For proper procedure in operating the test set, refer to Technical Manual for Test Set Transistor TS-1100/U, NavShips 93277.

FUNCTIONAL DESCRIPTION.–The block diagram (fig. 8-26) consists essentially of a reference oscillator, a tuned amplifier, and a variable bias supply. The oscillator is used to generate a test signal, the tuned amplifier is used to measure the second harmonic component of the current of the transistor under test, and the bias circuit furnishes the appropriate voltages to the transistor under test.

The reference signal source is a Hartley oscillator operating at a frequency of 1,125 Hz.

AT.113

Figure 8-26.—TS-1100/U, block diagram.

The transistor under test is biased for approximately class B operation. Thus, the transistor conducts only when the input signal level exceeds the work function of the emitter-base diode. The input signal is adjusted until the average collector current is 1 milliampere. The current passes through the collector load resistor, and a voltage is developed across it. This signal is first coupled through a high gain, narrowband amplifier, having a center frequency of 2,250 Hz, and then through a d-c microammeter. The amplifier gain has been adjusted so that the red line on the meter face corresponds to an average collector current of 1 milliampere.

The bandpass amplifier and meter are then switched across the base load resistor, and the meter then reads the magnitude of the average beta directly for a given transistor. Since the collector current is held constant for all transistors under test, the base current is inversely proportional to beta.

Direct measurement of the average collector and base current cannot be made on a d-c meter placed in series with these electrodes. This is because of the large errors which may result from the presence of "sneak paths" provided by the external network, since it is possible to have a direct current flow in these paths from the collector bias supply.

13357

By making an a-c measurement, the problems of erroneous direct current are eliminated, but others are introduced. If the a-c components of the collector current and base current were measured without filtering, the readout meter would not be able to differentiate between the normally rectified signal of the transistor and a nonrectified signal caused by the a-c sneak paths. To eliminate these erroneous signals, the second harmonic component of the signal current is measured.

TRANSISTOR CURVE TRACER (TEKTRONIX 575)

The Transistor Curve Tracer 575 is employed to plot or trace characteristic curves of transistors and other semiconductor devices. There are two different methods to plot the characteristic curves of a transistor. One is to apply d-c voltages and take measurements point-by-point. The other method is to use changing voltages and display the curve on an oscilloscope.

The 575 displays the curves by the use of the oscilloscope. There are several advantages in the use of the second method. To begin with, it is faster and more accurate than the point-by-point method. The point-by-point method may allow small irregularities in the characteristics to go undetected. Since heat is a major factor in transistor operation, errors caused by heat are reduced because the periods of applied power are shorter. Another definite advantage is that permanent records of the curves traced out on the oscilloscope may be easily produced at a reasonable cost by the use of photographic equipment.

This equipment is also provided with a self-calibration test. The operator can quickly reassure himself of the accuracy of the test set by the use of this built-in calibration check, in case a displayed curve deviates from the published nominal characteristic curve. The following paragraphs describe briefly how the 575 works and outlines a method for determining dial settings for transistors found in the fleet.

An illustration of the front panel of the equipment is shown in figure 8-27. As can be seen the controls are grouped into five blocks, with a test connector panel at the base of the test set. In addition to the block arrangement the panel is also color coded to simplify the operation. The collector currents and voltages are referenced by the sections of the panel etched in red; the sections etched in blue refer to the base currents and voltages. An exception to this color code is when a common base transistor configuration is being tested, at that time the blue is in reference to the emitter.

In the description of the five functional divisions that follows, refer to figure 8-27 for the item numbers listed; a functional block diagram is also given in figure 8-28.

The collector sweep circuit supplies the transistor under test with a collector voltage which is the output of a full-wave rectifier without any filtering. The 60-Hz line voltage is supplied to the full-wave rectifier and the output of the rectifier is 120-Hz pulses. The output waveform varies from zero volts to some peak value which can be controlled from the front panel (items 2 and 4). The peak voltage can be varied in two ranges, from 0 to 20 volts and from 0 to 200 volts. The polarity of the sweep voltage can be reversed in order to check both PNP- and NPN-type transistors (item 3). A variable amount of resistance can be placed between the collector sweep supply and the transistor under test in order to limit the maximum amount of collector dissipation (item 1).

Base Step Generator

The step generator develops currents and voltages which change value in stairstep fashion in synchronization with the collector sweep voltage (items 12, 16, 17, and 18). The output of the generator can be reversed in polarity and can be connected to either the base or the emitter of the transistor under test (item 13). The number of steps can be varied from 4 to 12 according to the type of display desired (item 14).

Display Function

The display function includes the three major functional blocks remaining; the vertical and horizontal amplifiers, and the cathode-ray tube. (A description of the operation of a cathode-

ray tube is given in Basic Electronics; an oscilloscope is also discussed later in this chapter.)

The horizontal and vertical amplifiers of the cathode-ray tube display can be driven by several different inputs, depending upon what characteristics are of interest (item 9). The horizontal amplifier can select any of four inputs and display one of them on the horizontal axis. The four inputs are base volts, collector volts, base current or base-source volts, and external. In the base volts position, the horizontal amplifier is connected to the base of the transistor under test. In the collector volt position, the horizontal amplifier is connected to the collector of the transistor under test. Both of these inputs have several positions so that the scaling factor can be changed. The base-current or base-source volts position connects the output of the base step generator into the horizontal amplifier. The external position connects the horizontal amplifier to two coax connectors on the rear of the instrument.

AT.115

Figure 8-28.–Transistor curve tracer block diagram.

The vertical amplifier can also select from four different inputs: collector MA, base volts, base current or base-source volts, and external. Base volts, base current or base-source volts, and external positions are the same as described for the horizontal amplifier, but in the collector MA position, the vertical axis will give a plot of collector current.

INTERPRETING THE DISPLAY.–As the collector voltage changes from zero to some peak value and back to zero again, the step generator output remains at some specific level and then changes to some new level for the next collector voltage cycle. The collector voltage is swept at a rate of 120 Hz, and the step generator changes steps or level after every cycle (in the 240 steps per second, the step generator changes at both the zero point of the collector sweep and at the maximum point). Figure 8-29 is a plot of collector sweep voltage and base step generator current. It should be noted that the collector sweep makes a complete excursion, while the base is at some steady value. As the next collector sweep starts, the base current is changed to the next value of current selected by the dials on the front of the instrument, and again the base current will remain steady while the collector voltage is varied.

13360

FIG. 2

1333 1933

AT.116

Figure 8-29.–Waveforms of collector sweep versus step generator current.

As previously mentioned, the waveforms of figure 8-29 can be reversed by switches on the front panel in order to check either PNP or NPN.

Figure 8-30 is a plot of collector voltage and collector current for given values of base current for an NPN transistor. For this type of transistor, it is a convention to have the lower left-hand corner represent zero collector voltage and current. In this graph, it was arbitrarily decided that each division to the right of the lower left-hand corner of the horizontal axis would represent a collector voltage change of one more volt positive. This would indicate a collector voltage swing of zero to 10 volts positive. The vertical axis is a plot of collector current varying from zero milliamperes in the lower left-hand corner to 10 milliamperes at the top of the graph in 1 milliampere steps. The different lines on the graph represent different values of base current; in this case, each line represents a change of 0.01 milliampere. If this graph had been for a PNP rather than for an NPN, the upper right-hand corner would have represented zero collector voltage and zero collector current. The divisions to the left would have represented negative collector voltage and the divisions downward from the top would have indicated the amount of negative current. This would have made the family of curves to appear as shown in figure 8-31.

These curves are known as the static collector characteristics for a common emitter configuration or output characteristics curve. Curves can be developed for common base and common collector also, but normally the information is available for the common emitter mode. Using this configuration, it is easier to check the transistor. To thoroughly describe how a transistor is going to work in a circuit,

AT.117

Figure 8-30.–Typical NPN collector curves.

AT.118

Figure 8-31.–Typical PNP collector curves.

13361

it is necessary to know the input characteristic curve as well as the output curve. The input characteristic curve is developed by plotting base current on the horizontal axis, base to emitter voltage (V_{RE}) on the vertical axis at different values of collector to emitter voltage (V_{CE}). Although it is necessary for the design engineer to know the input characteristic curve when designing a circuit, the output characteristic curve will normally give the maintenance technician enough information to allow him to evaluate a transistor.

Measuring Beta (h_{fe})

One means of measuring the quality of a transistor is the Beta (β) or current gain in the common emitter configuration. Mathematically, Beta is represented by the formula

$$\beta = \frac{\Delta ic}{\Delta ib}$$

where V_{CE} is constant. Beta is also called the forward current transfer ratio and represented by the symbol h_{fe}, which is derived from the hybrid equivalent circuit of a transistor. To determine the Beta from the output characteristics, measure the change in collector current between two values of base current at some constant collector voltage; for instance, in figure 8-30, to determine the Beta at a collector voltage of 5 volts, measure the change in collector current between the base current curves of 0.02 ma and 0.03 ma. In this example, the change in collector current measures 1 ma, so the Beta is equal to the change in collector current divided by the change in base current or

$$\frac{1 \times 10^{-3}}{0.01 \times 10^{-3}} = 100$$

Measuring I_{CO}

Another characteristic of a transistor is the I_{CO}, also called I_{CBO}. This is the collector current when the collector is biased in the reverse direction (high resistance, normal connection) with respect to the base, and the emitter is open-circuited. The I_{CO} of a transistor is highly temperature-dependent and the measurement made with the curve tracer will be at the ambient temperature only; but it is still significant. The method used to measure the I_{CO} is shown schematically in figure 8-32. Notice that the emitter is not connected.

The display of the curve tracer when measuring I_{CO} is shown in figure 8-33. The vertical axis indicates collector current, just as it did when Beta was being measured; but now the vertical amplifier is adjusted to afford maximum gain so that the small amount of current causes a noticeable deflection. The horizontal axis is still calibrated to show collector voltage.

The technician must know the Beta and I_{CO} of a transistor in order to tell whether or not the one he is testing is good. Since no manual describing the characteristics of different transistors is provided with the curve tracer, it is necessary to obtain this information from other sources. NavWeps 16-1-530 Replacement Guide, Semiconductor Device (Transistors and Semiconductor Diodes), dated May 1963, is an excellent source. For those transistors not listed in this publication, a specification sheet can be obtained from the manufacturer.

Section 1A of NavWeps 16-1-530 is a list of transistor replacements. Section 1A also gives the technical section in which a specific transistor is listed. These are Sections 2 through 10. To use this manual, look up the transistor in the technical section which applies; descriptions at the top of each page tell whether the transistor is germanium or silicon, PNP or NPN, low or high power. The important columns

AT.119

Figure 8-32.—Connections for checking I_{CO} (I_{CBO}).

13362

AT.120

Figure 8-33.–Typical display of $I_{CO}(I_{CBO})$.

in the technical section needed to obtain information on testing are MAXIMUM COLLECTOR DISSIPATION, ABSOLUTE MAX RATINGS, MAX I_{CBO} at MAX V_{CB}, Typical "h" Parameters at 25° C.

Under the column labeled Typical "h" Parameters, there is listed a typical h_{fe} or a minimum and maximum value of h_{fe} depending on which technical section the transistor is listed in. In the same column is listed the collector voltage and collector current at which this h_{fe} is to be obtained.

The collector voltage (V_{CE}) and collector current (I_C) provide the starting points from which to determine the curve tracer settings; for instance, if the V_{CE} is 5 volts, the horizontal amplifier would be set to COLLECT or VOLTS, 1 volt per division. This would place the 5-volt position in the middle of the display, and if the I_C is 1-ma, the vertical amplifier would be set to COLLECT or MA, 0.2 MA per division. This would place the 1-ma position in the middle of the display. The collector sweep can be determined from these settings, since the horizontal amplifier is set to 1 volt per division. The collector voltage varies a total of 10 volts, so the PEAK VOLTS RANGE is in the 0 - 20 position and the PEAK VOLTS control is set at 10. To determine the setting for the DISSIPATION LIMITING RESISTOR, obtain the maximum collector dissipation from the column in the technical section labeled MAX COLL DISS. This, in conjunction with the setting of the PEAK VOLTS control, can be plotted on the chart on top of the curve tracer to obtain the correct setting of the limiting resistor.

The step generator is set up in the following manner. The switch labeled REPETITIVE-OFF-SINGLE FAMILY is set to REPETITIVE, and the control labeled STEPS/FAMILY is set counterclockwise. This gives four steps per family, which is usually sufficient; but if more are desired, set STEPS/FAMILY to any value. The switch labeled POLARITY has a chart under it showing the correct position for NPN and PNP. Use the portion of the chart pertaining to grounded emitter-type circuits. The switch labeled STEPS/SEC can be in either of the two 120 positions or in the 240. The only difference in the two 120 positions is that at one of them, the step generator changes level when the collector is at zero volts; and at the other position, the step generator changes level when the collector is at the maximum voltage. In the 240 position, the step generator changes level at both the zero collector voltage and at the maximum point. The step selector can be set by starting at the smallest change per step (0.001 ma) and increasing the size of the step until the display has the necessary separation between the values of base current to determine Beta. In the alternative procedure, the Beta listed in the technical section can be divided into the amount of collector current and the result used as the setting of the step selector. If there isn't enough separation between the lines representing the base current to accurately determine the Beta, increase the amount of each base step until a good display is obtained.

To check the I_{CO} of the transistor, disconnect the emitter and change the current per division setting on the vertical amplifier to the most sensitive position (0.01 ma). Set the step zero very accurately, as described in NA 16-45-107, which is the Service Instruction Manual and Operating Instruction Manual for the curve tracer. After setting the step zero, note the difference between the step zero and

13363

the present position of the trace; this is an indication of the I_{CO}. The I_{CO} of the transistor is listed in the technical section, in the column MAX I_{CBO} at MAX V_{CB}, which describes the I_{CO} at BV_{CBO}—the breakdown voltage, collector-to-base with emitter open.

By measuring Beta (h_{fe}) and I_{CO} (I_{CBO}), a fair picture of the condition of a transistor is presented. There is one thing that should be mentioned in connection with the curve tracer, however; matching of transistors. Some Navy equipments have matched pairs of transistors, but unless the specifications are checked, it cannot be automatically assumed that Betas of the transistors are matched. Sometimes the Betas are matched, sometimes they are not; many times several characteristics are matched.

SIGNAL GENERATORS

The principal function of a signal generator is the production of signals having the specific characterstics required for the test or measurement in question. It is very important that the amplitude of the generated signal be correct. In many generators, output meters are included in the equipment so that the output may be adjusted and maintained at a standard level over a wide range of frequencies.

When using the generator, the test equipment output signal is coupled into the circuit being tested. Its progress through the equipment may then be traced by the use of high impedance indicating devices such as vacuum tube voltmeters or oscilloscopes. In many signal generators, attenuators are provided. These are used to regulate the voltage of the output signal and also provide correct impedance values for matching the input impedance of the circuit under test. Accurately calibrated attenuators are desirable since the signal strength must be regulated to avoid overloading the circuit receiving the signal.

There are many types of sinusoidal signal generators. It is possible to classify them roughly by frequency into audio generators, generators of both the audio and video ranges, radiofrequency generators, frequency-modulated RF generators, and special types which combine all of these frequency ranges.

In addition, signals other than sinusoidal are also generated for testing of equipment. The signal generators producing nonsinusoidal outputs are usually classified according to the type of signals they produce. Some signal generators produce several types of signal waveforms.

In almost all currently used types of signal generators, electron tube oscillators are used to produce the initial signal. In order to achieve accurate results in the use of the signal source, it is necessary to allow the oscillator circuits to reach a condition of stable operation before applying the output. This condition is reached when the tubes and circuit elements attain the temperature at which the instrument was calibrated.

A preliminary warmup should always be given the generator when accurate and stable signals are desired. The minimum warmup time for the generator is contained in the Service Instruction Manual for each model. The general properties and functions of signal generators are covered in Basic Electronics. In the sections immediately following, there is a discussion of several types of generators.

In testing the receiver section of a transceiver, the output of the signal generator is usually connected to the antenna terminal of the transceiver. If the transceiver is then keyed, damage to the signal generator results. This damage usually includes burning out of the resistive elements of the signal generator output circuits; these elements are rated only for the comparatively low power of the signal generator. In this type testing configuration, it is essential that some form of protection be given the test equipment.

One form of protection which can be provided is a fuse in series between the signal generator output terminal and the transceiver antenna terminal. The value of the fuse is dictated by the output limitations of the signal generator—usually about 1/16 ampere is recommended.

SINE WAVE GENERATORS

Sine wave generators will be discussed under the heading of three classes. These classes are audio, video, and radiofrequency. The sine wave generator is used to produce simulated conditions for the alinement and testing of equipments.

13364

Audio and Video

Audio signal generators produce stable audiofrequency signals used for testing audio equipment. Video signal generators produce signals which include the audio range and extend considerably further into the RF range. These generators are used in testing video amplifiers and other wideband circuits. In both audio and video generators, the major components include a power supply, an oscillator (or oscillators), one or more amplifiers, and an output control. Voltage regulation circuits are necessary to insure stability of the oscillator in generators which derive power from 115-volt, a-c sources. In portable generators, battery power supplies are usually used, and these require no voltage regulation.

In the audio and video generators of the beat-frequency type, the output frequency is produced by mixing the signals of two radiofrequency oscillators, one of which is fixed in frequency and the other variable. The difference in frequency of the two is equal to the desired audio or video frequency. For example, if the fixed and variable oscillators both produce a frequency of 400 kHz, the resultant output frequency is zero. If the variable oscillator is changed to 401 kHz, the resultant is then 1 kHz. By action of this type, any desired frequency in the range of the circuits may be produced in the output.

Audio signal generators often include RC oscillators in which the audio frequency is directly produced. In these, a resistance-capacitance circuit is the frequency determining part of the oscillator. The frequency varies when either the resistance or the capacitance is changed in value. In commercial generators, however, the capacitance alone is often chosen as the variable element. The change in frequency which can be produced by this method is limited, and it is usually necessary to cover the entire range of the generator in steps. This is accomplished by providing several RC circuits, each corresponding to a portion of the entire range of frequency values. The RC circuits in the oscillator are switched to cover the desired portion of the audio range.

The amplifier section of the block diagram of figure 8-34 usually consists of a voltage amplifier and one or two power amplifiers.

AT.121

Figure 8-34.–Block diagram of typical audio or video signal generator.

These are coupled by means of RC networks, and the output of the final power amplifier is often coupled to the attenuator, or output control, by means of an output transformer.

The output control section provides a means of matching the output signal to the input of the equipment under test and regulating the amplitude of the signal. The settings of the output control knob provide output voltage values which are either inscribed directly on the knob or which can be interpreted by reference to the instruction manual provided with the generator.

Radiofrequency

A typical radiofrequency signal generator contains, in addition to the necessary power supply, three main sections–an oscillator circuit, a modulator, and an output control circuit. The internal modulator modulates the radiofrequency signal of the oscillator. In addition, most RF generators are provided with connections through which an external source of modulation of any desired waveform may be applied to the generated signal. Metal shielding surrounds the unit to prevent the entrance of signals from the oscillator into the circuit under test by means other than through the output circuit of the generator.

A block diagram of a typical RF signal generator is shown in figure 8-35. The function of the oscillator stage is to produce a signal which can be accurately set in frequency at any point in the range of the generator. The type of oscillator circuit used depends on the range of frequencies for which the generator

13365

AT.122

Figure 8-35.–Block diagram of a radiofrequency signal generator.

is designed. In low frequency signal generators, the resonating circuit consists of one of a group of coils combined with a variable capacitor. One of the coils is selected with a range selector switch which attaches it to the capacitor to provide an LC circuit which has the correct range of resonant frequencies.

In signal generators designed for the higher frequencies, the resonating circuits are usually in the form of butterfly tuning circuits and resonant cavities. Reflex klystron oscillators are often used in generators of frequencies above 1000 MHz.

In any signal generator, it is required that the oscillators have good stability both in frequency and amplitude over a wide range of output frequencies.

The function of the modulating circuit is the production of an audio (or video) voltage which can be superimposed on the RF signal produced by the oscillator. The modulating signal may be provided by an audio oscillator within the generator (internal modulation), or it may be derived from an external source. In some signal generators, either of these methods of modulation may be employed. In addition, a means of disabling the modulator section is used whereby the pure unmodulated signal from the oscillator can be used when it is desired.

The type of modulation used depends on the application of the particular signal generator. The modulating voltage may be either a sine wave, a square wave, or pulses of varying duration. In some specialized generators, provision is made for pulse modulation in which the RF signal can be pulsed over a wide range of repetition rates and at various pulse widths.

Usually the output circuit of the generator contains a calibrated attenuator and often an output level meter. The output level meter gives an indication of, and permits control of, the output voltage of the generator by indicating arbitrary values of output read in tenths through the value of one.

The attenuator selects the amount of this output. The attenuator, a group of resistors forming a voltage-dropping circuit, is controlled by a knob which is often calibrated in microvolts. When the control element is adjusted so that the output meter reads unity (1.0), the reading on the attenuator knob gives the exact value (no multiplication factor) of the output in microvolts.

If output voltage is desired at a lower value, the control is varied until the meter indicates some decimal value less than one; this decimal is multiplied by the attenuator reading to give the output in microvolts.

SG-85/URM-25D.–RF Signal Generator Set AN/URM-25D is typical of most RF signal generators in common usage. It consists of Signal Generator SG-85/URM-25D, its case, and an assortment of accessory items.

It is intended primarily for bench testing of electronic equipment, covering the frequency range from 10 kHz to 50,000 kHz. This frequency coverage is accomplished in eight bands, and the RF output can be either modulated or unmodulated. The frequency generated can be read from a main frequency scale within an accuracy of ±0.5 percent; and by proper use of a 1-MHz internal crystal calibrator, the accuracy can be increased to 0.05 percent above 1 MHz.

This test set also generates an audio signal of 400 or 1000 hertz, which is used to modulate the RF carrier. The audio signals are also separately available at the front panel.

Operational procedure, technical characteristics, and theory of the SG-85/URM-25D can be found in NavShips 92134(A).

FM SIGNAL GENERATORS.–Frequency-modulated RF signal generators are widely used for testing frequency-modulated receivers and for visual alinement (using an oscilloscope) of AM receivers. A frequency-modulated signal is an alternating voltage in which the frequency varies above and below a given center frequency value. The overall frequency change is called the frequency swing.

13366

There are several methods by which the frequency of the oscillator in the signal generator may be frequency modulated. In one type of FM generator, use is made of a vibrating plate which forms one of the elements of the tuning capacitor of the oscillator to be modulated. The plate is driven by a device similar to a magnetic loudspeaker. The audio modulating voltage is applied to the driving coil which moves in the field of a permanent magnet and vibrates the plate of the capacitor at the applied audiofrequency. Movement of the plate causes variation of the capacitance in the oscillator tuning circuit with the result that the frequency of the oscillator is periodically raised or lowered.

Another method of producing frequency modulation is based on the action of a reactance tube which is connected in parallel with the tuning circuit of the oscillator to be modulated. A reactance tube is an electron tube in which the plate current is made either to lead or to lag the plate voltage variations by 90°. Because of this phase difference, the plate circuit of the tube is electrically equivalent either to a capacitor or to an inductance. The modulating voltage is impressed on the grid of the reactance tube, causing the capacitive (or inductive) reactance of the plate circuit of the tube to vary. Since the reactance tube plate circuit is a part of the oscillator tuning circuit, variation in the reactance value causes the generated frequency to vary in step with the modulating voltage.

In signal generators of microwave frequencies, frequency modulation is easily accomplished in the oscillator by applying the modulating voltage to the repeller plate of the reflex klystron tube which is usually employed in these generators.

SWEEP GENERATOR AN/URM-75

Sweep Generator AN/URM-75 is a versatile precision test instrument used for alining and checking radio receivers in the frequency range of 5 to 220 MHz. Its major component is the SG-93/URM-75 sweep generator, which supplies signals for the following functions:

1. Observing frequency response, relative gain, and bandpass characteristics of RF, IF, and video stages.
2. Alining RF and IF circuits.
3. Checking and adjusting discriminators.
4. Determining relative receiver sensitivity.

Basically, the unit consists of an FM sweep oscillator, a marker oscillator, a crystal oscillator, an audio oscillator, a frequency converter, a blanking circuit, and two output jacks.

The FM sweep oscillator is tunable over a frequency range of 50 to 220 MHz. In conjunction with the sweep converter stage, the oscillator produces a sweep signal which is variable from 5 to 220 MHz. This extended range is covered in two bands.

On band B, the sweep converter is disabled and the sweep oscillator operates alone to cover the range of 50 to 220 MHz. On band A, the sweep oscillator signal is beat against a 116.5 MHz signal from a fixed frequency oscillator in the converter stage. This beat produces a signal which is variable from 5 to 50 MHz. The sweep output is available at the MIXED OUTPUT jack. The signal may be used alone or in conjunction with a marker signal.

The marker oscillator operates over a frequency range of 4 to 220 MHz, covered in 6 bands. The marker signal, either modulated or unmodulated, is then supplied to both the MKR OUT jack and the MIXED OUTPUT jack. By means of this signal, the exact frequency may be determined for any point along a frequency response curve produced by the sweep signal.

The crystal oscillator is normally operated at a fundamental frequency of 10 MHz. By insertion of the appropriate crystal, however, oscillation may occur between 4 and 15 MHz. The crystal oscillator output, either modulated or unmodulated, is supplied to both output jacks. This signal provides a means of correctly calibrating the marker oscillator, or of calibrating external signals.

The audio oscillator generates a signal of 600 Hz which may be used to modulate the marker output and/or the crystal oscillator output, if desired. It is not available as a separate output.

The generator incorporates an optional blanking circuit which produces a 60-Hz sine wave. The positive half of the sine wave is

13367

eliminated, and the negative half is applied to the grid of the FM sweep oscillator. This input cuts off the FM sweep during the period of the half cycle. Thus, when the operator activates the blanking circuit, the FM sweep oscillator produces pulses of energy occurring at a 60-Hz rate.

PULSE GENERATOR AN/URM-44A

The generation of pulse signals involves many fundamental electronic circuits and some special purpose tubes. Some of the circuits involved are multivibrators, limiters, clampers, discriminators, oscillators, and sawtooth generators. One of the special purpose vacuum tubes is the reflex klystron, which is used as an oscillator.

The TS-622A/U is a typical pulse generator. It is the main component of Radio Test Set AN/URM-44A.

The TS-622 is a signal generator of low power output and is used in the maintenance of radio and radar equipment operating in the frequency range between 7,000 and 10,750 MHz. It produces continuous-wave, pulse-modulated, and frequency-modulated signals. The output frequency and power level of the test set are indicated on separate direct reading dials located on the front panel.

In the pulse-modulated mode of operation, pulse widths of 0.5 to 10 microseconds may be obtained, and the pulse repetition may be adjusted from 40 to 4,000 pulses per second. Pulse modulation is obtained from a multivibrator which produces square waves of the above mentioned pulse widths and frequency.

In the frequency-modulated mode of operation, a sawtooth generator supplies a sawtooth of voltage to the reflex klystron to cause the signal to be frequency modulated.

In the CW mode of operation, the klystron is permitted to free-run at the frequency selected.

This test set includes an internal synchronizing generator (the multivibrator), and has provision for applying an external synchronizing signal of either positive or negative polarity. It also has provision for an external modulating signal to be applied.

The front panel provides the following three outputs:

1. The RF output, which is the output from the klystron oscillator.
2. An undelayed sync (undelayed synchronizing voltage).
3. A delayed sync. The syncs are either the output from the internal sync generator or an input from the external sync source.

The Service Instruction Manual, AN 16-30URM44-2, contains a breakdown of all circuits of the test set and detailed theory of operation of each. Also included in the manual is a master block diagram to simplify the explanations.

PULSE GENERATOR AN/UPM-55

This equipment is basically a pulse generator and a synchroscope, combined into a single unit. It is used to generate, display, and measure pulse test signals. It consists of Pulse Generator SG-30/UP, its transit case, and the associated cables, adapters, accessories, and technical manuals. Operation of the equipment involves the use of high potentials which are dangerous to life. Safety precautions must be observed.

The Pulse Generator SG-30/UP has been designed to furnish rectangular voltages of adjustable duration, amplitude, and repetition frequency. These pulses are delayed so that they follow trigger pulses by an adjustable time interval. The equipment may be triggered by an external signal, or it may be triggered by an internally generated audio-frequency signal. Internally generated pulse, trigger, and audio signals are made available at output terminals on the front panel.

The synchroscope located in the same unit is capable of accurately determining the waveshape, amplitude, duration, and time relationship of the output pulses. The equipment is suitable for use in maintaining airborne or ground electronic equipment. The design and construction of the unit makes it adaptable for work performed in laboratories or in maintenance shops located aboard ship or on land.

MULTIPLE-SIGNAL GENERATORS

Signal Generator SG-321A/U provides multiple output signals which are essentially transient-free over a frequency range of 0.008

13368

to 1200 cps in 5 bands. The versatility of the equipment and the quality of its generated signals make the SG-321 useful for any general purpose testing application within its frequency range. It is especially useful in the testing of servosystems and mechanically operating systems, and in the electrical simulation of mechanical operations.

The outputs available from this equipment include square and triangular waveforms, both of which are inherent in the basic oscillating system. In addition, a sine wave is developed by modifying (synthesizing) the triangular waveform. A sync output pulse is also made available for external use.

The basic oscillating systems uses a type of relaxation oscillator that is especially well adapted to the generation of very low frequencies. Both the triangular and the square wave of voltage as a function of time are inherent in the systems.

Any type of AVC system causes a delay in the stabilization of an output response following a change in operating frequency. The oscillating system of the SG-321A/U is a constant amplitude device which requires no AVC system. The output amplitude and distortion of signals is therefore almost completely independent of frequency.

The signal generator is rated to deliver at least 30 volts peak to peak to a 4000-ohm load. The sync output is a negative pulse of 10 volts amplitude and a duration of less than 5 microseconds. The sync pulse occurs at the crest of the sine wave, and at corresponding points on the other waveshapes.

SIGNAL ANALYZERS

Signal analyzers, while used in many different situations, generally aid in the accomplishment of only one function, that is to check the response of an equipment under simulated conditions of specific operations.

MODULATION MEASUREMENT

Modulation characteristics can be determined by waveform measurement or by use of modulation meters (which are special applications of basic test equipment). Modulation measurements are sometimes required during tuning procedures to adjust transmitting equipment for the proper amount of modulation. During maintenance tests of modulated transmitter equipment, the amount of distortion of the output signal and the modulation level or index should be determined.

The modulation level of carrier signals in multiplexing equipment is usually set at the factory or in the shop during corrective maintenance procedures. Proper adjustment of the input signal level and automatic signal level regulation circuits provide the correct amount of modulation. Defects in modulation circuits can be detected by measurements of the quality of the received signals. Corrective maintenance analysis of multiplex equipment modulation circuits can usually be made by signal level measurements. Therefore, specific modulation measurements are normally not required for a carrier equipment which operates in the audiofrequency to medium frequency RF range.

Most amplitude modulated radio transmitters which operate in the low frequency to high frequency range must be adjusted for correct modulation during normal tuning procedures. If the modulation level is low, the transmitter is not operating at its maximum efficiency; on the other hand, modulation in excess of 100 percent procedures serious distortion. Since either of these conditions is undesirable, amplitude modulation should be maintained between 60 and 95 percent when possible. The modulator amplifier gain can be initially adjusted by use of an oscilloscope or a modulation meter.

The modulation level or index of AM and FM radio transmitters which operate in the VHF range is usually adjusted by the manufacturer or in the shop during corrective maintenance. Amplitude modulation of radio transmitters in this frequency range can usually be measured by the same methods employed for transmitters in the LF to HF range.

Frequency modulation measurements can be obtained by the use of an audiofrequency signal generator and a receiver with a beat-frequency oscillator. The modulation index can also be determined by a comparison method, using a frequency-modulated signal generator having a calibrated modulation control, an AF signal generator, a radio receiver capable of detecting FM signals, and an output signal level indicator.

13369

UNIT II - USE OF DRAWING INSTRUMENTS

Drawing Board and T-Square Lesson 1

OBJECTIVE: To learn how to maintain and use a drawing board and T-square.

RELATED INFORMATION:

FIG. 1

The drawing board shown (Fig. 1) is 18 inches wide and 24 inches long, a convenient size. It is made from well-seasoned basswood, joined together by tongue-and-groove construction. Either side may be used when drawing. Both its sides and edges should be kept free of dents, knife marks, and holes. Dampness or excessive heat will cause the board to warp; do not store it near a radiator. This board should be kept clean and free of pencil lines. It may be used on top of work benches or drawing tables when they are available.

The T-square shown in Fig. 2 is used for guiding the pencil when drawing horizontal lines, and for supporting the triangles when drawing vertical and oblique lines. It consists of a head and a blade with transparent edges. Care should be taken not to dent the edges, for smooth lines cannot be drawn against a dented edge. When not in use, the T-square is hung up, a hole in the blade being provided for this purpose. A good cleaning fluid such as carbon tetrachloride should be used to clean the T-square whenever needed, for a dirty instrument will smudge a drawing.

FIG. 2

AT.123

(A) Measurement of elapsed time;
(B) measurement of voltage difference.

small series resistor and look at the voltage wave across the resistor with the oscilloscope. Other quantities such as temperatures, pressures, speeds, and accelerations can be translated into voltages by means of suitable transducers, and then viewed on the oscilloscope.

Interpreting the Display

To find the elapsed time between two points on the graph (fig. 8-36 (A)) such as A and B, multiply the horizontal distance between these points in major graduated divisions by the setting of the TIME/DIV (time per division) control. This control sets the horizontal sweep rate of the oscilloscope. The distance between points A and B is 4.8 major divisions. If the TIME/DIV control is set at 100 microseconds per division, then the elapsed time between points A and B must be 4.8 x 100 = 480 microseconds. In general, elapsed time = horizontal distance in divisions X TIME/DIV setting.

If a MULTIPLIER control is associated with the TIME/DIV control, multiply the above result by the setting of the MULTIPLIER. If a MAGNIFIER is in operation, divide the result by the amount of magnification.

To find the voltage (fig. 8-36 (B)) difference between any two points on the graph, such as A and B, multiply the vertical distance between these points in major graduated divisions by the setting of the VOLTS/DIV control. This control sets the vertical deflection factor or sensitivity of the oscilloscope. The vertical distance between points A and B is 4.0 divisions: If the VOLTS/DIV control is set at 0.5 volts per division, then the voltage difference between points A and B must be 4.0 x 0.5 = 2.0 volts.

The quantity called pulse repetition rate (or pulse repetition frequency) for periodic pulses can be expressed as the number of pulses per unit of time. Examples: 10 pulses per second and 50 pulses per microsecond.

In using the oscilloscope to measure the frequency or repetition rate of periodic waveforms, first read the horizontal distance in major divisions between corresponding points on two succeeding waves. This is the horizontal distance occupied by one cycle of the wave. Multiply this by the setting of the TIME/DIV control in seconds, milliseconds, or microseconds. Take the reciprocal of this product; that is, divide it into 1. The result is the desired frequency or repetition rate.

It is convenient to use square waves, rather than other forms of waves, for testing of equipment because the nature of a defect, rather than simply its presence, is suggested by the kind of distortion which occurs to a square wave. By observing the squarewave response, it is easy to tell whether the transmission of low or high frequencies is affected. This observation is not so well separated with regard to frequency if waves other than square waves are used.

If two linear devices give identical responses when square waves are fed into them, they can, in general, be expected to give responses similar to each other when other waveforms are fed into them.

Information Contained in a Square Wave

It can be shown that a periodic wave contains the following components; (1) a fundamental wave, which is a sine wave having a frequency equal to the repetition frequency of the square wave, and (2) an infinite series of harmonics–sine waves having frequencies which are equal to whole numbers multiplied by

13371

the fundamental frequency. The harmonics must be properly related in phase and in amplitude to the fundamental.

Waveform D of figure 8-37 depicts a periodic rectangular wave (square wave). In the case of the square wave, the only harmonics present are the "odd" harmonics (those whose frequencies are equal to the fundamental frequency multiplied by odd whole numbers); and the strengths of the harmonics vary in inverse proportion to the frequencies of the harmonics, the fifth harmonic being one-fifth as strong as the fundamental, for example. The way in which these waves combine to make up a square wave is suggested by figure 8-37.

The four curves shown in figure 8-37 illustrate the following:

1. Curve A the fundamental sine wave.
2. Curve B the sum of the fundamental and third harmonic.
3. Curve C the sum of the fundamental plus third and fifth harmonics.
4. Waveform D is the ultimate square wave.

It will be noted that the first few harmonics combine with the fundamental to provide an approach to an actual square wave. Additional harmonics, of higher frequencies, would cause the leading edge of the wave to rise more rapidly, and produce a sharper corner between the leading edge and the top of the wave. It would require an "infinite" range of harmonics to produce a truly vertical leading edge and an actual sharp corner, and this situation is physically impossible to produce. But waves can be generated which are very close to this ideal situation. (The same considerations apply to the falling edge of the waveform, and the following corner.)

Information regarding the amplitude and phase relationships of the higher harmonics is, then, contained in the leading-edge steepness and in the sharpness of the corner.

If low frequency components (fundamental and the first few harmonics) are not present in the proper amounts and in the correct phase relationships, the part of the square wave affected will be the flat top. Figure 8-38 (A) shows the location of the low and high frequency information in a square wave. Low frequency defects will appear in the form of slope or general curvature in the top, as shown in (B) and (C) of the figure. In (B) of the figure, the low frequency components have leading phase angles and are attenuated. In (C) the low frequency components have lagging phase angles and are accentuated.

Oscilloscope Block Diagram

Figure 8-39 is a block diagram of a typical oscilloscope, omitting power supplies. The

AT.124

Figure 8-37.–Addition of harmonics to fundamental waveform.

AT.125

Figure 8-38.–Information found in a square wave.

waveform (A) to be observed is fed into the vertical amplifier input. The calibrated VOLTS/DIV control sets the gain of this amplifier. The push-pull output (B and C) of the vertical amplifier is fed through a delay line to the vertical deflection plates of the cathode-ray tube.

The time base generator or "sweep generator" develops a sawtooth wave (E) that is used as a horizontal deflection voltage. The rising or positive-going part of this sawtooth, called the "runup" portion of the wave, is linear. That is, it rises through a given number of volts during each unit of time. This rate of rise is set by the calibrated TIME/DIV control. The sawtooth voltage is fed to the time base amplifier. This amplifier supplies two output sawtooth waveforms (G and J) simultaneously–

AT.126

13373

one of them positive-going, like the input, and the other negative-going. The positive-going sawtooth is applied to the right-hand horizontal deflection plate of the cathode-ray tube, and the negative-going sawtooth is applied to the left-hand deflection plate. As a result, the cathode-ray beam is swept horizontally to the right through a given number of graduated divisions during each unit of time, the sweep rate being controlled by the TIME/DIV CONTROL.

In order to maintain a stable display on the cathode-ray tube screen, each horizontal sweep must start at the same point on the waveform being displayed. To accomplish this, a sample of the displayed waveform is fed to a "trigger" circuit which gives a negative output voltage spike (D) at some selected point on the displayed waveform. This triggering spike is used to start the rising portion of the time base sawtooth. As far as the display is concerned, then, "triggering" can be taken as synonymous with the starting of the horizontal sweep of the trace at the left-hand side of the grid.

The rectangular "unblanking" wave (F) derived from the time base generator is applied to the grid of the cathode-ray tube. The duration of the positive part of this rectangular wave corresponds with the duration of the positive-going or rising part of the time base output, so that the beam is switched on during its left-to-right travel and is switched off during its right-to-left retrace.

In many cases the leading edge of the waveform being displayed is used to actuate the trigger circuit. Yet it may be desirable to observe this leading edge on the screen-and the triggering and unblanking operations require a measurable time (P), often about 0.15 microsecond. To permit the leading edge to be seen, a delay (Q) of about 0.25 microsecond is introduced by the delay line in the vertical deflection channel after the point where the sample of the vertical signal is tapped off and fed to the trigger circuit.

The purpose of the delay line is to retard the application of the observed waveform to the vertical deflection plates until the trigger and time base circuits have had an opportunity to begin the unblanking and horizontal-sweep operations. This permits viewing the entire desired waveform—even though the leading edge of that waveform was used to trigger the horizontal sweep.

If the delay line were not used, only that portion of the waveform following the instant (T) in waveform (A) could be seen.

Oscilloscope Probe

The input circuit to the vertical amplifier of an oscilloscope can be simulated by a high resistance R shunted by a small shunt capacitance C, as shown in figure 8-40.

AT.127

Figure 8-40.—Oscilloscope vertical amplifier input circuit.

In some applications, even this high resistance and small capacitance can produce undesirable loading upon the circuit whose waveforms are being examined by means of the oscilloscope. This loading can cause the oscilloscope presentations to be different from the waveforms that would be present with the oscilloscope disconnected. One use of a passive probe is to reduce this resistive-capacitive loading on the circuit under investigation.

The probe includes a resistor R_p shunted by a capacitor C_p, (fig. 8-41). This combination is connected in series with the inner conductor of the cable to the oscilloscope input. The result is that, when the probe is connected to the circuit under investigation, there is connected to that circuit a new effective loading capacitance smaller than the original capacitance C and a new effective loading resistance larger than the original resistance R. Thus the loading effect of the

13374

AT.128

Figure 8-41.–Oscilloscope vertical amplifier using a passive probe input.

oscilloscope input-circuit on the circuit under investigation is reduced through the use of the probe.

A second effect of the probe is to reduce the amount of signal voltage applied directly to the oscilloscope input connection for a given amount of original signal voltage. This occurs because of the voltage-divider action of R_p and R. This effect is taken into account in the "attenuation ratio" marked on the probe. Thus if the probe is marked "10X ATTEN" all oscilloscope voltage indications must be multiplied by 10.

If an oscilloscope equipped with a probe is used to look at a square wave, and the probe capacitor C_p is too small, some of the high frequency components of the square wave will be bypassed around the oscilloscope input terminals by the input capacitance C. Thus the steepness of the leading edge of the displayed square wave is reduced. (See fig. 8-42 (A)).

If the probe capacitor is adjusted to the correct value, a compensating amount of high frequency information is bypassed around the probe resistor R_p to make up for the loss through C, and the leading edge of the displayed square wave will be restored to its original steepness (B). If C_p is made too large, the high frequency response of the circuit will be overcompensated and apply too much high frequency information to the oscilloscope input connection. This results in an overshoot in the displayed waveform that was not present in the original (C). C_p can be adjusted to its correct value by using the probe to display the square wave generated by the voltage calibrator that is a part of the oscilloscope. Adjustment is made to display a square wave with as flat a top as possible.

AT.129

Figure 8-42.–Effects of probe adjustment.

Probe adjustment must be checked whenever a probe is used with an oscilloscope or a plug-in preamplifier that has an input capacitance different from that of the instrument with which the probe was previously used.

NOTE: As indicated in figure 8-42, the attenuation achieved is a result of R as well as R_p, which means that, though probes may be swapped for use with other types of oscilloscopes, the calibration may be in error, even though the waveform distortion may possibly be adjusted out.

AN/USM-140B Oscilloscope

The front panel arrangement of a dual-channel oscilloscope that was especially designed for general purpose use is shown in figure 8-43. Most of the controls and connectors normally used by the operator are indicated in the figure and are self-explanatory. Those that are not are listed and described below.

CALIBRATOR switch (item 2): This switch is used to control the output of the self-calibrator which supplies a 1-kHz signal used as a standard to check the accuracy of the vertical and horizontal sensitivity selectors. The signal is available at either of the two connectors just below the switch depending on the amplitude required. Amplitude of the signal is controllable from 0.2 millivolts to 100 volts.

ASTIGMATISM control (item 7): This control adjusts the sharpness of the trace. It is used in conjunction with the focus control.

Figure 8-43.–Oscilloscope AN/USM-140B.

POLARITY switch (item 9): This switch selects the type of input coupling. Either capacitive for a-c signals or direct for d-c signals. Channel B has an identical control.

GATE OUTPUT (item 14): The gate output provides a +50-volt unblanking pulse during horizontal sweep time.

SWEEP OUTPUT (item 16): The sweep output provides a voltage ramp of approximately -50 to +50 volts coincident with the horizontal sweep.

TRIGGER SOURCE (item 19): The trigger source selects the source of the signal to be used to trigger the sweep.

SWEEP MODE (item 20): The sweep mode provides a variable sensitivity adjustment for the sweep circuit. It also allows for the selection of either a triggered or a free running sweep.

TRIGGER SLOPE (item 21): This switch selects the portion of the waveform used to trigger the sweep either positive or negative.

This instrument is a high-speed, precision oscilloscope for displaying the waveforms of electrical voltages that range from a frequency of 22 megahertz to direct current. Vertical deflection sensitivity ranges from 20 millivolts to 200 volts per centimeter. Horizontal deflection sensitivity ranges from 0.1 volt to 100 volts per centimeter at frequencies from direct current to 1 megahertz per second.

The sweep generator, which is a part of the horizontal deflection system, provides a vari-

13376

able range of sweep times to allow the operator to display one or several cycles of the waveform, as required. The sweep rates are adjustable from 0.1 microsecond to 5 seconds per centimeter. A vernier control in the sweep circuit can be used to extend the slowest sweep to 15 seconds per centimeter. The sweep can be synchronized by an external signal or by the signal being viewed. Polarity and sensitivity of synchronization are selectable to permit synchronization from different points on complex waveforms. Sweep rate, expansion, and sensitivity are direct reading controls and are provided with potentiometer type continuous adjustment between each of the calibrated step selections.

Two identical probes with a 10 to 1 attenuation are provided in addition to an assortment of connector adapters and two coaxial cables to facilitate connecting the oscilloscope to the variety of equipment with which it can be used.

Maintenance of the oscilloscope by operating personnel is limited to checking and adjusting vertical sensitivity and balance, cleaning the air filter in the cooling air inlet, and replacing fuses. In many cases a calibration adjustment is required when replacing tubes and semiconductors. Therefore, only qualified technicians should attempt replacement of such parts. Operating personnel other than those qualified to make calibration adjustments should refrain from repair of this type except in an emergency.

The useful life of an oscilloscope can be materially extended by using normal care in handling and operating. When in use, the area behind the cooling air inlet must be kept clear to allow flow of the cooling air through the ventilating door. This oscilloscope is provided with a thermal switch to protect it from overhearing. If the instrument goes off during use, removal of the dual trace preamplifier plug-in unit will allow the operator to view a neon type indicator lamp. If the lamp is lit, the oscilloscope is overheated. Turn off the power and investigate the cause of overheating.

CAUTION: This instrument contains voltages as high as 8,600 volts, which can be fatal. Turn the instrument off before touching any internal part.

SYNCHROSCOPE

The synchroscope, which is widely used in radar testing, is an adaptation of the oscilloscope. A trace is produced only when it is initiated by an input trigger, as contrasted with the continuous sawtooth sweep provided by the oscilloscope. Synchroscope circuits are similar to oscilloscope circuits except for the signal channel and the sweep channel. These circuits are shown in block diagram form in figure 8-44.

The signal channel of a typical synchroscope includes an input circuit, which is usually in the form of a 72-ohm adjustable-step attenuator. Various degrees of attenuation are available, and the dial is calibrated to indicate how much attenuation is present. The attenuator insures that all signals, regardless of amplitude, produce approximately the same input level to the amplifier section.

Following the attenuator is an artificial delay line, which is a low pass filter with a cutoff frequency higher than the highest frequency to be passed, and which has an impedance of 72 ohms. The delay line is terminated with a 72-ohm gain control. One purpose of the delay line is to delay presentation of the signal to be observed until the sweep trace has been initiated by an undelayed portion of the input signal. If the delay line were not used, the initial portion of the waveform would not appear on the trace, because a certain amount of time is required for the input signal voltage to rise to the level needed to trigger the sweep circuit. With the delay line in use, the signal does not reach the amplifier until one-half microsecond after the trace starts; as a result, the entire pulse is seen. A secondary purpose of the delay line is to provide, by means of reflection, a series of accurately spaced pulses suitable for calibration of short time intervals.

To accomplish the secondary purpose, a switch is provided to cause a mismatch in the termination of the delay line. When a sharp pulse is applied into the line, a series of reflections occurs similar to those shown in figure 8-45. Since the time required for a pulse to travel down the line and back is 1 microsecond, a series of pulses occurring 1 microsecond apart is produced. Each successive pulse is smaller because of the losses in the delay line, but enough pulses

13377

AT.131

Figure 8-44.–Typical synchroscope, block diagram.

are visible for most high speed calibration purposes.

The gain control feeds a wideband or video amplifier, which is connected to the vertical deflection plates. In addition, an external connection is provided to the vertical plates.

The horizontal circuit consists of a sync switch for either internal or external sync, a sync amplifier with a gain control, and a start-stop sweep generator, which will not develop a sweep voltage until a pulse of sufficient amplitude is supplied. The duration of the sweep, or sweep speed, is made adjustable from a very few microseconds to about 250 microseconds. The sweep generator is followed by a conventional horizontal amplifier. Since the trace is triggered by the input signal, the synchroscope may be used to observe nonperiodic pulses, such as those occurring in a radar system with an unstable PRF generator.

AT.132

Figure 8-45.–Pulse reflection on a mismatched line.

In later designs, it is common to find provisions for calibration of input voltages and sweep time. Voltage calibration is made by comparing the unknown voltage with a variable-voltage pulse of known value, generated internally. The calibrating pulse is adjusted to be equal in amplitude to the unknown voltage; the value is then read from the dial that controls the calibrating pulse. Sweep time calibration is made with the aid of marker pulses produced by accurately adjusted tuned circuits. The marker pulses appear on the trace as a series of bright dots spaced at intervals chosen by the operator. In a typical synchroscope, marker intervals of 0.2, 1, 10, 100, and 500 microseconds may be selected in accordance with the time duration of the pulse under test; for greater accuracy, interpolation may be used.

13378

SPECTRUM ANALYZER

During the modulation of a radiofrequency carrier wave by keying, by speech or music, or by pulses, the resulting wave contains many frequencies. The original carrier is present, together with two groups of new frequencies called the sideband components. One group of sidebands is displaced in frequency below the carrier. The other group is displaced above the carrier. The distribution of these frequencies when shown on a graph of voltage or power against frequency is called the spectrum of the wave.

A spectrum analyzer is a device for exhibiting the spectrum of modulated waves in the radiofrequency range and in the microwave region.

In principle, the spectrum analyzer operates by tuning through the frequency region in question, using a narrowband receiver. The output of the receiver is measured, usually by means of a cathode-ray oscilloscope, and the plot on the screen is a graph of voltage versus frequency.

The device is essentially a superheterodyne receiver with a very narrowband intermediate frequency amplifier section. The local oscillator frequency is varied between two values at a linear rate. The frequency-control generator which governs the frequency of the local oscillator also produces the horizontal sweep voltage for the cathode-ray tube deflection plates. (See fig. 8-46.) As a result, each position of the beam corresponds to a definite frequency value; and the display is a graph in which the X-axis is interpreted in terms of frequency.

The output of the detector in the receiver is amplified and applied to the vertical deflection plates so that the beam is deflected vertically by an amount proportional to the voltage developed in the detector (and amplifier).

The signal to be analyzed is fed into the mixer stage of the receiver. The local oscillator changes in frequency at a linear rate, beating with each of the signal frequency components in succession to form the intermediate frequency of the narrowband amplifier. The output of the IF amplifier is detected, amplified, and applied to the vertical deflecting plates.

Spectrum analyzers designed for analysis of microwave signals are equipped with klystron tubes in the local oscillator stage. In analyzers

AT.133

Figure 8-46.–Typical spectrum analyzer, block diagram.

13379

adapted for lower frequency RF signals, triode oscillators are used which are varied by means of reactance-tube modulators.

Spectrum analyzers are employed extensively in studying the output of pulse radar transmitter tubes such as the magnetron. In this kind of analysis, unwanted effects such as frequency modulation of the carrier can be easily detected. In pure amplitude modulation of a carrier wave by a square pulse, the spectrum is symmetrical about the carrier frequency. Lack of symmetry indicates the presence of frequency modulation. A spectrum representing the ideal condition is shown in (A) of figure 8-47.

Examples of undesirable magnetron spectra are shown in (B) and (C) of figure 8-47. These forms indicate trouble in the modulator, the tuning system, or in the magnetron tube itself.

The carrier frequency is best defined as the center frequency in a symmetrical spectrum such as that shown in (A) of figure 8-47. In some analyzers this principle is used as a means of carrier frequency measurement. A sharply resonant circuit is provided in the receiver which acts as a trap to prevent an extremely narrow range of frequencies from appearing in the output of the IF amplifier. The result of its use is that a gap appears in the display, and the gap corresponds to the resonant frequency of the trap. The adjustment of the trap is calibrated in frequency, and the circuit can be adjusted to make the gap occur in the center of the spectrum. The frequency of the carrier is then read from the calibration of the trap.

For an additional coverage of spectrum analyzers, consult Basic Electronics, NavPers 10087-B. Also, a discussion of spectrum analyzers appeared in the June 1963 issue of the DIGEST. That article is recommended for personnel desiring additional information concerning this class of test equipment.

AT.134

Figure 8-47.–Frequency spectra.

WAVE ANALYZER

The wave analyzer is used to measure amplitude and frequency of the components of a steady state complex electrical waveform. These include the components of harmonic distortion, intermodulation distortion, hum, and noise.

Specific uses of the wave analyzer include the measurements of distortion components in AF equipments; radio receivers and transmitters; oscillators, amplifiers, and vacuum tube circuits in general; harmonic studies of electrical power system and electrical machinery, hum measurement in a-c operated communication equipment; and noise analysis. As a sharply tuned voltmeter, it is useful in the measurement of the transmission characteristics of electric wave filters and as a null detector for impedance bridges. The unit may be used as a detector for intermodulation distortion measurements when a two-signal audio generator is used as a source.

The wave analyzer discussed in the following paragraphs is a heterodyne type vacuum tube voltmeter. The IF amplifier includes a selective filter using three quartz crystals. The use of a heterodyne method makes it possible to vary the frequency response while using a fixed frequency filter.

The output of the local oscillator and the whole of the complex waveform to be examined are fed to a balanced modulator where their combination produces both sum and difference frequencies, or sidebands in the output. The original of the complex waveform is not passed by the modulator intermediate frequency output transformer and the local oscillator carrier frequency is suppressed in the output because of the two-tube, balanced modulator employed.

The 50-kHz component of the upper sideband, proportional to the voltage of that frequency present in the original wave to which the main dial is set, is selected and amplified by the intermediate stages. The step attenuators provide for measurement of a wide range of voltages.

The equipment is mounted in a shielded oak cabinet, and all critical parts are hermetically sealed.

13380

Fig. 3 shows the position of the hand and pencil for drawing horizontal lines. Note that the pencil is inclined in the direction the line is drawn, that is, towards the right.

FIG. 3

Caution must be taken when using the T-square in that the head must be placed flat against the left edge of the board if you are right handed, or against the right edge of the board if you are left handed.

White or buff drawing paper of various standard sizes is used at first for the required drawing plate. This is because this type of paper is easy to work with and it is comparatively inexpensive. Blueprints, however, cannot be made from this paper because it is not transparent. Therefore when blueprints are desired, a tracing of the drawing must be made on transparent paper. Later, projects may be drawn directly on tracing paper, which is the accepted method used in drafting rooms.

Scotch drafting tape (Fig. 4) is used instead of thumb tacks to fasten paper to the drawing board. Thumbtacks mar the board and are difficult to remove. A $\frac{1}{2}$-inch length of tape across each corner is sufficient to fasten the paper to the board.

FIG. 4

QUESTIONS:

1. Which side of the drawing board should be used when drawing?

2. In storing a drawing board, why should dampness and excessive heat be avoided?

3. What are the uses of the T-square?

4. Why should you avoid denting the edges of the T-square?

5. Why clean a T-square regularly?

A detailed discussion of wave analyzers is beyond the scope of this training manual, but the foregoing discussion should serve to familiarize the technician with some of the basic principles used in the design of a wave analyzer.

MULTIPLE-FUNCTION EQUIPMENT FOR SYSTEMS TESTING

The numerous and complex operations required for servicing and maintaining radar requires, in some instances, numerous classes of test equipment. Therefore, a test set such as the UPM-32, combining the functions of several test sets, is very practical. This combination test set performs most of the functions necessary for radar maintenance in its frequency range.

This test equipment (fig. 8-48) is portable and is designed primarily for use with radar systems operating in the frequency range of 8,500 to 10,500 MHz. It functions as a power meter, a frequency meter, a spectrum analyzer, a signal generator, and a general purpose syn-

1. Cable assembly.
2. Gaskets.
3. Test antenna.
4. Adapters.
5. Waveguide.
6. RF cable.
7. Power cable.

AT.135

Figure 8-48.–Radar Test Set UPM-32.

chroscope. The general capabilities of the test set are as follows:

1. Measurement of power, frequency, spectrum, and frequency pulling of conventional and multipulsed radar transmitters.
2. Measurement of sensitivity and bandwidth of a radar receiver.
3. Measurement of the frequency and spectrum of a radar receiver's local oscillator.
4. Adjustment of a radar receiver's local oscillator.
5. Measurement of TR recovery time.
6. Observation of video signals.
7. Providing pulsed, FM, or CW microwave signals.

Radar Test Sets AN/UPM-32 (for X-band radars) and AN/UPM-44C (for S-band radars) are very similar in function and in operation. Each is usable for the same general functions. Both are generally reliable instruments, but are susceptible to mixer crystal damage due to improper manipulation of the control. For this reason, every technician should receive a thorough indoctrination in the proper use and operation of these equipments when they are available in his particular shop. Although this requirement is generally applicable for all test equipment (and other electronic equipments), it is especially important in equipments where the probability of damage from improper operating procedures is so great.

LINE TEST EQUIPMENT

The purpose of this section is to discuss some of the more common test sets that are used during line maintenance by Organizational Maintenance Activities. It is not intended that this discussion be all inclusive of all line test equipment, but only some of the more common line test sets.

The majority of line test equipment are of the GO - NO GO type. In other words, the test set indicates that the electronic system under test does or does not meet the minimum acceptable standard. Some of the more intricate line test equipment can be used to determine faulty units (black boxes) of a system. Operational tests of a system after installation of a repaired unit may also be made with this type of test equipment.

IFF

Radar Test Set AN/UPM-8B is a portable, a-c operated instrument, designed to perform rapid preflight checks of installed transponders, such as those of the Mark X IFF system. Its testing capabilities include checking the above transponders when they are operated in association with Selective Identification Feature (SIF) coding equipment, such as Coder Group AN/APA-89. The following features of transponders or associated SIF equipment can be checked simultaneously:

1. Transmitted frequency.
2. Relative transmitter power output.
3. Decoding of mode 1, 2, or 3 interrogations (challenges).
4. Reply coding (number but not spacing of pulses for Mark X).
5. Receiver frequency.
6. Relative receiver triggering level.
7. Proper code configurations (when SIF equipment is employed).
8. Pulse spacing (when SIF equipment is employed).

The results of these checks are simultaneously resolved into a single REJECT or ACCEPT indication of an operating panel meter. The REJECT-ACCEPT meter on the operating panel may also be used to give an indication of the general operating condition of the test set itself.

TACAN

Radio Test Set AN/URM-101A is a lightweight, easy-to-use unit developed to provide preflight check of the normal operation of airborne TACAN sets. The test set may be hand-carried to the vicinity of the aircraft equipped with the radio set and placed on the deck, or any other suitable support. During operation of the test set, visual and aural indications at the radio set will enable an observer to determine, whether the radio set is operating properly. The test set receives from and transmits to the TACAN radio set either by radiation from the antenna or by a direct connection with a coaxial cable. The test set will operate with up to four TACAN radio sets simultaneously.

The test set simulates signals such as those produced by Radio Beacon Set AN/URN-3, and

which would normally be received by airborne TACAN sets at a particular bearing and distance from the beacon set. The test set generates a continuous tone signal, which provides aural indication when received. The test set transmits a continuous pulse train consisting of main and auxiliary reference pulse groups (bursts), identity pulses and equalizing pulses. In addition, when interrogated, it introduces reply pulses delayed to simulate distances of 5 miles and 100 miles. All of these pulses are amplitude-modulated with 15 and 135 hertz sine waves and are synchronized to give a bearing display of 140° on the airborne azimuth indicating equipment. A power output level control adjusts the RF unit to a constant power output, which is indicated on a panel meter. A range switch sets the desired 5-mile or 100-mile delay.

RADAR

The echo box is used in field testing, troubleshooting, and adjustment of pulsed type radar systems. Although simple in construction and operation, it is versatile in its applications. Properly used within its design limitations, the echo box can frequently eliminate the need for a complex test setup and an elaborate step-by-step testing procedure. The echo box uses passive circuitry, which does not require any external power (other than that of the radar set whose signal is to be analyzed). External power requirement is a critical factor with most other test sets.

The echo box is similar to a tuned cavity frequency meter, with additional capabilities. The tuned cavity frequency meter can be used to measure the frequency of CW or pulsed RF signals in the microwave range. The echo box, however, has no practical application in the testing or analysis of CW equipment signals. Figure 8-49 indicates the basic functional elements of a typical echo box.

Energy from the radar transmitter is fed through the directional couplers to the resonant cavity. When the cavity length is properly adjusted, resonant oscillations are set up by each

AT.136

Figure 8-49.–Typical echo box, functional circuit.

successive pulse of microwave energy. Maximum amplitude of oscillation occurs when the cavity is tuned precisely to the signal frequency. These cavity oscillations are detected by the crystal diode and indicated on the meter as an average d-c current. The amplitude of oscillation and the average current reading are proportional to the transmitter power output.

Oscillations in the tuned cavity are also coupled back to the radar set under test, where it is processed as an echo signal. This signal, when viewed on the indicator CRT, permits analysis of the radar pulse, and presents an indication of the general operating condition of the radar set.

Due to the manner in which the energy builds up in the cavity, saturation of the cavity is possible. If saturation does occur, distortion of the waveform and erroneous values of the measurements result. If the directional couplers do not prevent cavity saturation, additional attenuation must be provided.

A fairly complete functional analysis of the operating condition of a radar set can be obtained through analysis of the displayed waveform. Among the most important of the factors that can be determined are frequency and bandwidth, power and frequency spectra, sensitivity, pulse width and condition, and recovery time. Analysis of the waveform can also prove helpful in locating the cause of malfunctions within the radar set.

It must be remembered, however, that the echo box presents only relative (rather than absolute) values of power and sensitivity, and only rough values of frequency. Accuracy of these quantities is not comparable to the corresponding values obtainable from a spectrum analyzer. The primary value of the echo box lies in its regular usage. For maximum benefit, the values obtained from a given test must be compared to corresponding values obtained from a test on a radar set known to be operating properly.

In general, however, the echo box is an extremely valuable instrument. When used in a continuing maintenance program, it can enable the operator to maintain his equipment in peak operating condition. It can also provide him with indications of deterioration before actual malfunctions occur.

For personnel desiring additional information concerning echo boxes, the October 1965 issue of the DIGEST is recommended.

ALTIMETER

Delay Line MX-1381/APM-66 (fig. 8-50) is a portable unit of the Radar Test Set AN/APM-66 and consists of a coaxial cable delay line and two horn-type antennas. The two horns are connected together by a length of RG-55/U cable that is wound on two drums within the unit.

When the delay line unit antennas are mated with the altimeter receiver-transmitter antennas, the RF output of the transmitter is fed into one of the horn antennas, passes through the coaxial cable to the other antenna, and is fed out to the receiving antenna of the altimeter where it arrives delayed in time by an amount that is equal to the propagation time (electrical length) of the coaxial cable. This produces an altitude signal in the altimeter that is identical to that produced in normal altimeter operation when the altimeter is at an altitude that yields the same total propagation time down to the terrain and back again. Since two-way propagation is involved in normal operation, the altitude signal produced by a delay line will be equal to one-half the electrical length of the cable.

The length of the coaxial cable required for a delay line of this type may be determined from the formula:

$$L = V \times \text{altitude} \times 2$$

Where

L = physical length of the cable

V = velocity of wave propagation of the cable.

The delay line contains 228 feet of cable (330 electrical feet) and produces an altitude signal of 165 feet. The total attenuation of the cable and the two antenna horns is such that the altimeter that produces an altitude indication of 165 feet, minus the residual altitude, when coupled to the delay line can be considered as having adequate sensitivity for normal flight operation.

AT.137

Figure 8-50.–Delay line MX-1381/APM-66.

TEKTRONIX TYPE 453 OSCILLOSCOPE

The Tektronix Type 453 Oscilloscope is a lightweight, transistorized portable oscilloscope which has high frequency capabilities. The input signal range is from d.c. to 50 MHz. Input power to the scope is either 115 volts a.c. or 230 volts a.c. at line frequencies from 45 to 440 Hz. The power consumption is approximately 100 watts.

Some of the capabilities of the 453 Oscilloscope are as follows:

1. Display of two independent sweep signals simultaneously.
2. Display a signal which has an intensified portion, and this portion is also displayed as a complete separate sweep.
3. Various-time measurements.
4. Peak-to-peak signal measurements.
5. Voltage measurements of any point of a signal.
6. Voltage comparisons.
7. Frequency measurements.
8. Phase difference measurements.
9. Rejection of unwanted signals.

12285

CHAPTER 9

ELECTRONIC PRINCIPLES

This chapter is intended to provide an introduction to some of the more important topics and principles of electronics which do not fit into any specific chapter of this manual. In some cases, the information is of a general nature, applicable to many systems or equipments. In other instances, the data are based on relatively new developments and concepts which have not as yet reached the point of general applicability.

MODULATION AND DEMODULATION

Modulation is a process that permits the transmission of intelligence by superimposing it on an RF carrier. The carrier is normally of a constant frequency and amplitude; modulation varies one or more characteristic of the carrier in accordance with the intelligence to be transmitted. The characteristics of the carrier which may be varied are the amplitude, frequency, and phase. The type of modulation is designated by the particular characteristic which is to be varied. Demodulation is a process by which the intelligence is extracted from the transmitted wave and reproduced either in its original form or in some other form.

There are many ways to impose the intelligence on the carrier. In radiotelegraphy the operator depresses a key (switch) which activates the transmitter as long as the key is depressed. In radiotelephony the transmitter is operative as long as the microphone is activated; the sound picked up by the microphone is converted into an electrical signal and superimposed on the carrier. In radar the transmitter is activated automatically and regularly by pulses from the synchronizer. Regardless of the method of modulation, the modulating circuit functions to change the a-c output of the carrier generator in accordance with the instantaneous values of the intelligence signal. The demodulator (detector) must be matched with the system so as to respond to the particular type of modulation used.

MODULATION SYSTEMS

Each type of modulation has its own specific advantages and disadvantages, its own characteristics, and its own applications. In the discussion which follows, several types of modulation are compared.

The original and still the most commonly used type is amplitude modulation. Its major disadvantage is its susceptibility to noise. In order to overcome this disadvantage, frequency modulation is becoming more popular. Closely resembling frequency modulation is the process of phase modulation, a system which is not in common usage.

Amplitude Modulation

The RF carrier portion of the amplitude modulated wave is of fixed frequency and constant amplitude. An audiofrequency modulation signal is superimposed on the carrier in a manner that causes the amplitude of the carrier to vary, leaving the carrier frequency unchanged.

An amplitude modulated wave is composed of a number of frequencies, as shown in figure 9-1 (A) and (B). These frequencies are the carrier, the audio signals, the sum frequencies, and the difference frequencies. In the example, the frequencies are indicated as frequency bands on a spectrum graph because of the complexity of the audio signals, which normally include an enormous number of individual frequencies.

AT.138

Figure 9-1.–Signal spectrum, comparison.

The sum and difference frequencies are known as the sidebands, and carry the intelligence. When an RF carrier is modulated by a voice signal or by music, the side frequencies constitute a band of frequencies above (the sum) and below (the difference) the carrier. The width of each band is determined by the highest and lowest frequencies included in the modulating signal. The overall bandwidth required in the transmitter and the receiver is determined by the difference between the low end of the lower sideband and the high end of the upper side band. As each sideband contains identical infromation, the sidebands are redundant with only one sideband and the carrier being needed in AM detection.

Single Sideband

Single sideband has proved to be a more efficient and reliable means of voice communications, than has amplitude modulation. Efficiency has been improved by the concentration of the entire transmitter RF output into a single frequency spectrum rather than the division of power by the AM transmitter into a lower sideband, a carrier, and an upper sideband. This division of power in an AM transmitter results in less RF energy available at the AM receiver for detection of the modulated audio than would be available at an SSB receiver if a single sideband transmitter were being used.

In a single sideband system, the audio spectrum is mixed with an RF carrier in a balanced mixer. The output of the balanced mixer contains the carrier frequency minus the audio signal (lower sideband, LSB) and the carrier frequency plus the audiofrequency (upper sideband, USB). The design of the balanced mixer is such that the carrier frequency is suppressed. The output of the balanced mixer is applied to a mechanical filter which passes only one sideband. The output of the mechanical filter is essentially the audiofrequency translated up to the carrier frequency, plus or minus the audiofrequency. (See fig. 9-1 (C).) Transmitter and receiver bandpass is determined by the upper and lower limits of the sideband transmitted.

The sideband is thus heterodyned up to the desired operating frequency, amplified in the transmitter power amplifier, and fed to an antenna. Sideband power applied to the antenna is greater with single sideband than with AM because all transmitted power is contained within a single sideband. (Either sideband may be used.)

To receive a single sideband signal, it is necessary to translate the signal back to the original audiofrequency intelligence signals. The carrier frequency, which was removed at the transmitter prior to radiation, is generated locally at the receiver and mixed with the received sideband signal. The result of this mix-

ing is the original audio signal, which is subsequently separated from the RF in the detector.

Frequency Modulation

In frequency modulation the carrier amplitude remains constant and the output frequency of the transmitter is made to vary about the carrier (or rest) frequency at a rate corresponding to the audiofrequencies of the intelligence signals.

The extent to which the frequency changes in either direction from the unmodulated carrier frequency is called the frequency deviation (fig. 9-1 (D)). It corresponds to the change of signal amplitude in AM.

In frequency modulation systems there is no "percentage of modulation" to correspond with that of AM systems. The frequency deviation is dependent on the design of the specified equipment and is only indirectly determined by the modulating signal.

The ratio of the maximum frequency deviation to the audiofrequency of the modulating signal is called the modulation index, or deviation ratio. Allowable frequency deviation is determined by the frequency separation of adjacent channels, and this maximum deviation and the frequencies involved in the intelligence signals combine to determine the maximum modulation index.

Phase Modulation

In phase modulation, the instantaneous phase relationship between the modulated signal and the unmodulated carrier is varied. During a change in phase the instantaneous frequency of the signal also changes, so that the two methods (phase and frequency) are quite similar. Identical receivers may be used to receive either phase modulated or frequency modulated transmissions. Since phase variations are essentially equivalent to frequency variations, phase modulators are commonly used to develop FM signals.

Although the end result is essentially the same, phase modulation has the advantage that the carrier frequency can be stabilized (for example, with a crystal oscillator), while in FM the RF must be permitted to change in frequency during modulation.

Frequency-Shift Keying

Transmissions used in radioteletype, facsimile, and some data link equipments utilize a modulating system known as frequency-shift keying. In this equipment a keyer replaces the oscillator of a conventional CW transmitter. The keyer supplies a source of RF excitation that can be shifted slightly either up or down (or both) in order to make a distinction between pulses and spaces.

During unmodulated (continuous wave transmission) frequency-shift operation, the transmitter operates with a specified carrier frequency. When a MARK on a PULSE is to be transmitted, the transmitter frequency is shifted slightly (usually downward). In the three-level type operation (which is not in common usage at present), the frequency is shifted in one direction for a digital ONE, in the opposite direction (by the same frequency deviation) to represent a ZERO.

HETERODYNING

Heterodyning is a process by which two or more frequencies are combined in a nonlinear device so as to develop a composite output. In a heterodyne circuit (mixer) the frequencies involved are the original input frequencies, the sum frequency, and the difference frequency. (The modulation systems thus far discussed involve heterodyning action.) A nonlinear device is required to provide the mixing action; in a linear device, no mixing takes place.

Heterodyning is also involved in the creation of the intermediate frequency in receivers. In this application, the incoming modulated signal is mixed with the constant frequency out of the local oscillator. The result is the IF.

PULSE MODULATION

An example of pulse modulation systems is the conventional radar set. A pulse of short time duration is developed in a synchronizer, and is used to trigger the transmitter. The transmitter operates for the duration of the pulse input, and then rests until the next input once again serves to trigger it into operation. This intermittent operation of the transmitter permits the trans-

mission of relatively large values of power for short times (peak power), while allowing a long rest period to keep the average power within the limitations of the equipment.

Pulse modulation is also employed in the operation of computers and in digital data transmission systems. These topics are developed in some detail in various chapters of this manual; the current discussion is intended primarily to present some details regarding the pulses involved in the systems. (In connection with the discussion, make frequent reference to fig. 9-2.)

The main characteristics of a pulse are based on time, general shape, and magnitude of voltage or current change. For purposes of this discussion, the pulse is assumed to be a theoretical square wave of positive-going voltage. (This is the type pulse most commonly used in radar modulators, as well as in digital data systems, computers, etc.) It is further assumed that all actions are initiated by a trigger pulse which occurs at a TIME ZERO reference.

Since the pulse represents a change of voltage level, some passage of time is required for this change to occur. Although this elapsed time is undesirable in most applications, it is unavoidable. For purposes of this analysis, the pulse may be divided into three parts: leading edge, top, and trailing edge. Normally it is desired that the leading and trailing edges be as sharp as possible, and that the top be flat. The terms used in the discussion and indicated on figure 9-2 are fairly well standardized in pulse applications. Each time increment gives a direct indication of the quality of operation of the circuitry involved in the use or generation of these pulses.

Pulse Duration and Magnitude

The duration of a pulse is normally considered to be the time interval between the 50 percent points in the rise and fall of voltage levels. (Some references use the 90 percent points for this consideration.)

The magnitude of a pulse is the difference in voltage level between the maximum (signal) state and the minimum (quiescent) state.

AT.139

Figure 9-2.–Pulse characteristics.

Leading Edge

The leading edge of a pulse is that portion which represents the increase of voltage from the quiescent level to the stabilized maximum level. In some pulses there is some overshoot and revovery (not shown in fig. 9-2); these increments are included in the leading edge.

Following the initiating action of the trigger pulse, the voltage level begins to rise. The DELAY TIME represents the period required for the pulse to reach 10 percent of its ultimate magnitude. Until the 10 percent value is reached, it is assumed that the pulse amplitude is not sufficient to perform its normal functions. Delay time is the result of the time required for the active components of the circuit (transistors or vacuum tubes) to switch from one state to the other.

The RISE TIME represents the period required for the pulse to increase from 10 to 90 percent of its ultimate magnitude. This increment is normally associated with the charging of lumped or distributed capacitances or the building of magnetic fields within various circuit components. In practical waveform analysis this is the period usually used to describe the steepness of the leading edge of the waveform.

Once the pulse has reached 90 percent of its ultimate magnitude, it is considered to be fully capable of performing all the functions required of the pulse.

Trailing Edge

The trailing edge of a pulse represents the return of voltage from the stable operating level to the stable quiescent level. It includes any overshoot and recovery which may be present.

In computer work, the interval during which the pulse decreases from 90 to 50 percent of its maximum value is referred to as the STORAGE TIME. It is during this time that the pulse is usually routed to the memory unit.

The FALL TIME (or the DECAY TIME) denotes the period during which the pulse voltage decreases from 90 to 10 percent of its maximum value. It includes storage time. The fall time interval is normally used to evaluate the quality of the trailing edge.

Once the pulse has decreased to the 10 percent level, it is considered incapable of performing its assigned functions.

Pulse Top

The pulse top refers to that portion during which the voltage level remains relatively constant at its high signal value. The term may be used to refer to the pulse segment falling between the 90 percent voltage points. More commonly, however, it is used to refer to the portion between the first attainment of maximum voltage level to the beginning of the rapid decline in voltage.

In most pulses, once the voltage has reached its maximum level, it tends to decrease slightly during the "flat" portion. The longer the pulse duration, the more drastic this deterioration usually becomes. The deterioration is frequently the result of capacitor charge leakage. Whatever the cause, in radar transmitters this decrease in voltage level of the modulator pulse may result in a change in the operating frequency and/or the output power of the magnetron.

PULSE-TIME MODULATION

Pulse-time modulation is a refinement of the pulse modulation technique. In pulse modulation, the transmitter is keyed or triggered; in pulse-time modulation, this triggering is encoded in some manner involving time. In this system the timing of the pulse is part of the intelligence to be conveyed, and compatible pulse-time circuitry is required to extract the intelligence from the wave.

An example of pulse-time modulation is the TACAN system (discussed in some detail in chapter 17 of this manual.) In this system, the transmitter sends out a comparatively large number of pulses, most of which are meaningless. The only pulses which convey intelligence are those with a definite time relationship to each other. A receiver which does not have a compatible decoding circuit would be incapable of demodulating the signal and using the information.

Digital computers and data transmission systems use a somewhat different version of pulse-time modulation. In these equipments,

13390

6. Why do we use white or buff drawing paper?

7. Why do we use Scotch drafting tape to fasten the drawing to the board?

ASSIGNMENT:

Fasten an $8\frac{1}{2}$" x 11" piece of buff drawing paper to the board. Beginning from the top and using your T-square, draw horizontal lines $\frac{1}{2}$-inch apart across the paper until the sheet is filled. Within one of the $\frac{1}{2}$-inch spaces, draw three horizontal guide lines $\frac{1}{8}$ inch apart and proceed to letter as previously instructed, your name, address, and the alphabet.

the coding is accomplished by converting the intelligence into binary form and routed as a pulse or no-pulse train.

In both examples, the timing of the pulses conveys an integral part of the intelligence, but the methods and meanings are different. In the TACAN system, randomly-spaced pulses constitute most of the transmitted signal; in digital work the pulse and no-pulse intervals are evenly spaced and controlled by "clock pulses."

DEMODULATION

As mentioned previously, a nonlinear device is required to modulate a carrier frequency. A nonlinear device is also required to demodulate that carrier in order to extract the intelligence from it. Detectors, crystal mixers, discriminators, and coincidence gates are examples of circuits used as demodulating devices.

Demodulation is a process by which the intelligence superimposed on the carrier is removed and reconverted into the original modulating signal.

ELECTROMAGNETIC RADIATION

A general discussion of wave motion is presented in chapter 5 of this manual. Basic Electronics contains a basic discussion of the radiation of electromagnetic waves. Certain aspects of radio waves, especially those applicable to radio direction finding equipment, are discussed briefly in chapter 17 of this manual.

The current discussion of electromagnetic wave radiation is intended as a brief summary of the data contained in those sources. It is also an expansion of some specific topics dealing with the general subject. The discussion is limited primarily to radio waves, and includes general characteristics, propagation principles and methods, and polarization techniques.

CHARACTERISTICS

Electromagnetic waves are complex waves. They consist of two mutually perpendicular fields—electric and magnetic. They travel at a relatively constant velocity of 300,000,000 meters per second in space, and at a slightly different velocity in other media. They tend to travel in a theoretically straight line in a direction which is mutually perpendicular to the two component fields. They are, however, subject to reflection, refraction, diffraction, and absorption (with or without reradiation).

The frequency spectrum of electromagnetic waves extends from somewhat below 30 kHz upward to some unspecified limit. The usable spectrum is being extended in both directions as new developments occur. The spectrum includes those frequencies generally called radio waves, heat, infrared, light, ultraviolet, X-rays, etc. Each broad division of the spectrum possesses easily distinguishable characteristics as well as characteristics common to all electromagnetic waves.

Figure 9-3 is an illustration of the spectrum of electromagnetic wave radiation, with the broad limits of each band designated. The limits of the band are more or less arbitrarily chosen for convenience—there is no sharp division between adjacent bands.

PROPAGATION

As discussed in Basic Electricity, NavPers 10086-B, an electric current flowing in a wire sets up a magnetic field about that wire. If the current is alternating, the magnetic field will expand and collapse, reversing direction in synchronism with the current which produced it. If this alternating magnetic field cuts a wire, it will produce an alternating current in that wire.

The principles of the radiation of electromagnetic energy are based on the laws that a moving electric field creates a magnetic field, and a moving magnetic field creates an electric field. The created field is always in time phase with its parent field, but it is perpendicular to it in space. These laws hold true whether a conductor is present or not.

In systems making use of electromagnetic waves in the radiofrequency spectrum, an antenna is used to convert electric current into fields for transmission, and to convert fields into electric current during reception. Basically, an antenna is a conductor or a system of conductors which serves to radiate or to intercept waves of electromagnetic energy. Basic theory of operation of antennas is dis-

193 OF 327

NATIONAL BUREAU OF STANDARDS-1963-A

cussed in Basic Electronics, and a discussion of several major types of antennas may be found in chapter 11 of this manual.

POLARIZATION

Polarization of an electromagnetic wave is the directional characteristic of the electric and magnetic fields of the wave. In general usage, the electric field is used as the reference. The polarization phenomenon is found throughout the entire range of known electromagnetic radiations.

The type and direction of polarization are defined by looking at the polarization vector in the direction of propagation, rather than by looking at the wave as it approaches the observer. Polarization is frequently classified as linear (horizontal or vertical), or circular, depending on the direction of the electric field. In linear polarization the field is considered to maintain a constant direction; in circular polarization it is considered to rotate as it progresses away from the propagating antenna.

As the wave travels through the atmosphere or ionosphere, it is reflected and refracted by particles and other electromagnetic fields. This results in rotation of the polarization from its original state. In addition, a second component appears that follows a different path, with attenuation and phase shift characteristics different from the original wave. The result is an elliptically polarized wave. In recently modified theories, the linear and circular polarization are considered as special cases of an elliptically polarized wave.

Unpolarized Waves

In an unpolarized electromagnetic wave, the electric field appears to have random orientation with respect to the earth's surface. In a plane perpendicular to the direction of propagation, the electric field seems to have approximately equal magnitude in all directions. Radiation from atomic or nuclear processes is normally unpolarized; thus, ultraviolet, visible light, and infrared radiations emanating from heated bodies, electrical discharges, or nuclear agitations are normally unpolarized.

Polarized Waves

In a polarized wave, however, the orientation of the electric field is completely predictable. Electromagnetic waves originating in vacuum tube or transistor oscillators, resonant cavities, etc., are always polarized. The electric vector of the wave may lie in a plane with a constant relationship to the propagation, or the electric field may tend to rotate about the axis of propagation as it travels away from the transmitting antenna.

The initial polarization of a radiated wave is a function of the orientation of the radiating antenna. The shape of the antenna, the distributribution of current and voltage, and the radiation characteristics of the antenna determine the polarization with respect to the antenna. The orientation of the antenna with respect to the surface of the earth then determines the polarization of the wave with respect to the earth.

AT.140

Figure 9-3.—Spectrum of electromagnetic waves.

193

Vertical Polarization

An electromagnetic wave cannot be propagated without both the electric and the magnetic fields. A propagated wave has both a groundwave (or direct) component and a skywave (or reflected) component. At frequencies up to about 1500 kHz, the groundwave is generally more useful than the skywave. At the time of transmission, the two components are indistinguishable; the groundwave is simple that portion of the transmitted wave that travels along the surface of the earth and the skywave is that portion that does not. Thus, the polarization of the two components is exactly the same at the time of transmission.

A dipole antenna mounted so that its physical axis is vertical to the earth's surface propagates vertically polarized waves. That is, the electric field is vertical and the magnetic field is horizontal.

The earth's conductivity determines the rate of attenuation of the groundwave. With perfect conductivity no horizontal component of the groundwave could be sustained, because the earth shorts out any horizontal component of the electric field. The earth, however, is an imperfect conductor, so the horizontal component of the electric field in the groundwave is attenuated at a rate depending on the conductivity of the earth in the local area.

With horizontal polarization, this condition results in a proportionately large loss of the signal. With vertical polarization, however, the portion of the wave front traveling along the surface is slightly retarded. This causes the wave front to lean slightly in the direction of propagation; it thus tends to follow the curvature of the earth, extending the range of the groundwave.

At frequencies below 1500 kHz, the groundwave permits the use of vertical polarization for long range communications. At higher frequencies, the groundwave component is more greatly attenuated, with a consequent decrease in maximum effective range obtainable from the groundwave component of the wave front. However, the higher the frequency, the less the wave front tends to lean. Therefore, progressive increase in frequency approaches line-of-sight transmission, rather than following the earth's curvature.

Horizontal Polarization

At higher frequencies (or when skywave operation is desired), horizontal polarization is normally used. This condition permits attenuation of the groundwave, as previously mentioned, but has little effect on the skywave component. Long range coverage is obtained by using the reflective and refractive properties of the ionospheric layers.

At frequencies above about 30 MHz, however, the skywave is not returned to the earth's surface, so the range is decreased considerably and tends toward line-of-sight coverage.

Use of the skywave component creates problems of polarization shift. These problems are discussed later in this section under the heading of elliptical polarization.

Circular Polarization

Circular polarization describes an electromagnetic wave whose electric and magnetic fields rotate about the axis of propagation, maintaining their perpendicular relationship. This rotation is, in effect, similar to the rotating magnetic field of a polyphase a-c motor. Two-phase motors use two alternating currents of the same frequency but with a 90° phase relationship to supply two field windings which are physically oriented at right angles to each other. If the two currents are of the same frequency, equal magnitudes, and 90° phase displacement, the resultant field will rotate in direction and maintain a constant magnitude.

Circular polarization of electromagnetic waves may be obtained through the use of two linearly polarized dipole antennas mounted physically at right angles and supplied driving signals 90° displaced in phase. In actual practice the same signal may be used to excite both antennas, with the phase displacement resulting from use of different lengths of transmission line. If the transmission line to one antenna is effectively a quarter-wavelength longer than the transmission line to the other antenna, proper phasing is obtained.

The resultant wave rotates at the same frequency as the driving signal, and maintains a constant magnitude; it is thus circularly polarized. Direction of rotation is determined by the

time sequence of the signals to the separate antennas.

Optimum reception of circularly polarized waves requires the use of a receiving antenna which is circularly polarized in the same direction as the wave. Nonrotation or rotation in the opposite direction results in cancellation of components of the received signal.

One important practical application of the use of circularly polarized waves is found in some search radar equipment. Circular polarization of the radar beam provides the advantage of reduced echo magnitude from rain. This advantage is not obtained without some decrease in returns from other targets. When using circular polarization, rain echoes are reduced by approximately 20 db; however, normal target returns are also reduced–by approximately 3 db. This results in a loss of about 18 percent in usable radar range. Circular polarization should therefore be used only when the radar targets would otherwise be lost in the rain returns.

Elliptical Polarization

A circular wave can be thought of as consisting of two linear waves, as indicated previously. An elliptical wave can similarly be thought of as consisting of two circular waves. An elliptically polarized wave may also be considered as a wave produced by two unbalanced linear waves, as described in the following discussion.

The same elements which were described for the circularly polarized wave may be used to describe the elliptically polarized wave. If the signal applied to one antenna is attenuated as well as delayed, unequal drive and unequal radiation result. Under these conditions rotation still occurs, but the magnitude of the resultant wave is not constant. A graph of the strength of the radiated signal resembles an ellipse. The same condition may be obtained by changing either the physical orientation of the dipole antennas or the phase relationship of the two feed signals.

It has been mentioned that all electromagnetic waves may be considered to have elliptical polarization, with linear and circular polarization being merely special cases. It has also been stated that the use of the reflective and refractive properties of the ionosphere introduced polarization shifts and rotations that may offer problems. The following paragraphs discuss these topics.

Assume a wave which is polarized perfectly horizontal with respect to the earth's surface. Unless the ionosphere is also perfectly horizontal and of perfectly uniform density, the reflection or refraction is nonuniform. The nonuniformity results in the introduction of a second factor which tends to react with the main wave.

The interaction between the original wave and a reflected or refracted wave tends to change the phase relationship of the two wave components. Changing the phase relationship results in some degree of rotation, effectively changing the polarization of the wave in the field of radiation. Thus the wave may be polarized horizontally as it leaves the transmitter antenna, but vertically polarized by the time it reaches the receiving antenna.

In actual practice, the shifting occurs to some degree in all propagated waves. Atmospheric and ionospheric particles and extraneous electromagnetic fields react with the signal wave to produce a constantly changing wave polarization. If the total rotation-producing forces cancel, the resultant wave is linearly polarized; if they are of equal magnitude and proper phasing, circular polarization results.

FREQUENCY

As previously discussed, propagated electromagnetic waves of various frequency ranges exhibit certain characteristics which may not be important at other frequencies. Alternating currents and voltages which are not propagated also exhibit characteristics which are peculiar to the frequencies involved.

EFFECTS OF INCREASING FREQUENCY

At frequencies normally designated as "power" frequencies, circuit components (resistors, capacitors, and inductors) are invariably lumped quantities. That is, the values of the components are considered to be constant, and are relatively easy to calculate. They are based primarily on the physical dimensions of

13394

the components themselves, and are not appreciably affected by other circuit elements.

As frequency is progressively increased, however, the apparent values of these components change, and the total effect of the components in the circuit cannot be explained by the lumped values alone. Distributed and stray values of resistance, capacitance, and inductance become relatively large with respect to the lumped values, and must be considered. With increasing frequency, these values become progressively more important in determining overall circuit parameters and circuit operational characteristics.

Distributed properties may be defined as the resistance, capacitance, and inductance spread uniformly along the entire length or area of a circuit element. Stray properties refer to the resistance, capacitance, and inductance which exist between a given circuit element and all other objects and between the circuit element and ground.

For example, a 1/4-inch diameter copper rod 4 inches long, placed in free space where no external influences are present, would possess small but definite values of R, C, and L. If the conductor were cut in half, each part would have exactly half the previous values. In other words, the distributed properties are uniform as long as the conductor itself remains uniform in cross sectional size, shape, and conductivity, and provided that no external influences exist. If the conductor is not uniform, the distributed properties still exist, but their distribution is not entirely uniform.

If the conductor is placed in an actual circuit, it retains these distributed properties, and it also acquires stray properties because of its closeness to other components in the circuit. These stray and distributed properties exist in all conductors and conducting elements. They even exist in lumped property components and in the leads. At power frequencies, the distributed and stray values are so small compared to the lumped values that they may be conveniently ignored. In fact, it is usually practical to ignore these values at frequencies up to about 30 MHz, except in such circuit elements as self-resonant sections of transmission lines and antennas.

At frequencies above about 30 MHz, however, distributed and stray values may become so large (compared to the lumped values) that they can no longer be ignored. This happens because of a double-ended change which takes place in circuit elements. On the one hand, increasing the frequency of operation usually requires smaller values of lumped properties. On the other hand, increasing the frequency results in greater interaction between each circuit element and the other components in the circuit. In addition, the actual values of R, C, and L contained in a given component are not constant–they tend to change when frequency is varied. The following paragraphs discuss the changes which occur, and the effects of these changes on circuit operation.

Inductance

The term "distributed inductance" refers to the self-inductance distributed along the length of any type of conductor, whether it is or is not meant to act as an inductor. Inductance, as defined in Basic Electricity, NavPers 10086-B, is the property of a conductor that tends to oppose any change of electron flow (current) through the conductor. Inductance reveals itself only when current is varying in the conductor; a back emf (electromotive force) is induced in a direction that tends to oppose the change in current flow. Even a very short section of straight wire possesses self inductance. The conductor does not have to be wire, however; it can be any conductor, any shape or size.

Usually, the actual amount of self-inductance is small, but its effect becomes important at frequencies above 30 MHz. The effect may be desirable or unwanted, but it cannot be ignored. A complex equation is needed to find the actual value of self-inductance, but the important point here is that the value depends directly on the number of lines of flux surrounding the conductor. Self-inductance is highest at the center of any conductor carrying alternating current, and tapers off toward the outside surface. This is the cause of skin effect, explained later.

UNDESIRABLE EFFECTS.–The property of distributed inductance can cause serious RF losses if leads and connecting linkages are not kept as short as possible. Figure 9-4 demonstrates how this loss takes place. The plate

13395

tank circuit (A) is designed to operate at a frequency of 4 MHz. The inductor is connected to the tube plate by a wire having a self-inductance of approximately 0.1 microhenry (μh).

Ignoring loading and other factors, calculation shows that the resistive impedance offered by the tank circuit at reasonance is 4,710 ohms, where the inductive reactance ($X_L = 2\pi fL$) of the connecting wire is approximately 2 ohms, and is so small in proportion to 4,710 ohms that it can be neglected at this low frequency.

When the operating frequency is raised to 100 MHz (fig. 9-4 (B)), the inductance of the tank coil must be reduced to resonate at the higher frequency. At 100 MHz, the self-inductance has decreased slightly but the increase in frequency raises the inductive reactance of the plate lead to 59.6 ohms. The resistive impedance of the tank circuit is still 4,710 ohms at resonance. A voltage divider effect occurs, which prevents the entire RF signal output of the tube from being impressed across the tank circuit and results in a loss of gain. In addition, the introduction of an inductive component causes a phase lag that is undesirable in certain applications. At higher frequencies, the effect becomes even more pronounced, introducing larger losses.

AT.141

Figure 9-4.–Inductance at high frequencies.

DESIRABLE EFFECTS.–In certain circuits, a condition of series or parallel resonance is desired, and the property of distributed inductance, distributed capacitance, or a combination of both, may be used to achieve this. For example, to provide a bypass for signal voltages from the low-impedance end of an IF tank circuit back to the cathode of the tube, a series resonant circuit offers the lowest impedance path. When the IF is above 30 MHz, it is possible to get the effect of series resonance by cutting the leads of the capacitor to lengths offering the necessary series inductance. This is shown in figure 9-5 (A). Note that the capacitance is lumped, but the inductance is the distributed inductance of the capacitor leads. (See fig. 9-5 (B).) However, the signal voltage sees a certain value of each property, regardless of whether the properties are lumped, distributed, or any combination thereof.

INDUCTIVE COUPLING.–When a conductor carrying alternating current runs sufficiently close to another conductor, its magnetic field induces an electromotive force in the second conductor, causing a current to flow. This is the effect of mutual or stray inductance.

The study of mutual inductance and coupling at lower frequencies usually is restricted to coils and transformers, but above 30 MHz the effect of coupling between two conductors–even two straight pieces of wire–becomes important. This is true because the amount of coupling or mutual reactance between two inductors increases as the frequency is increased, if the physical relationship remains the same.

Some effects of coupling between distributed inductances are undesirable. For instance, if the grid and plate leads of a single tube amplifier stage are permitted to run close to each other, signal energy from the plate circuit may be coupled back to the grid, causing either regeneration or degeneration. Distributed capacitance also is present, but only the inductive coupling effect is considered at this time. As another example, a current-carrying wire may be too near a tube shield, inducing an emf that causes current to flow in the shield. This current flow through the shield is a power loss that can be supplied only from the current-carrying wire.

TECCI
AD-A 13396

When inductive coupling causes circuit imbalance or power loss, it usually is spoken of as stray coupling. The amount or degree of coupling depends directly on the relative positions of the conductors as well as their distance from each other. Figure 9-6 shows the effect of physical position on the degree of coupling. In (A) the coupling is loose, inasmuch as the leads are crossing at right angles, and minimum mutual inductance results. The coupling

AT.142

Figure 9-5.–Series self-resonance.

AT.143

Figure 9-6.–Inductive coupling effects.

13397

between the wires (B) and (C) increases because of the greater amount of mutual inductance. Practical circuits are laid out with the shortest possible leads, well separated from one another, and distant from the chassis and shields. If two wires must cross, they should cross at right angles, because this produces the smallest mutual inductance.

Capacitance

The term "stray capacitance" refers to the capacitance between any point on a conductor and all surrounding objects. Capacitance exists between any two points that are at different electrical potentials. This is true whether the points of different potential are in different conductors or in the same conductor. Although the distributed self-capacitance of a conductor is of relatively little importance, except in special circuits, the effect of the stray capacitance between two conductors must be taken into consideration at higher frequencies. This is because of the capacitance that exists between the parts of circuit elements and the electrodes of electron tubes, as well as between leads and switch contacts.

The actual value of capacitance changes only slightly with frequency, but the reactance changes greatly. The formula for capacitive reactance $\left(X_C = \frac{1}{2\pi fC}\right)$ shows that, if the value of capacitance remains the same, increasing the frequency causes the capacitive reactance to decrease. Therefore, a small value of distributed capacitance at the lower frequencies offers a high reactance to the flow of a.c., but at higher frequencies it offers a lower reactance. This effect is often undesirable when it occurs accidentally between two conductors in a circuit, but may be used deliberately to achieve series or parallel resonance in resonant line sections. The losses in distributed capacitance are lower than those in lumped capacitors because the dielectric is usually air, instead of a solid, and because the RF resistance (discussed later) and distributed inductance values are smaller.

UNDESIRABLE EFFECTS.–An example of the manner in which stray capacitance may upset the proper operation of a circuit is shown in figure 9-7.

Assume that C_d represents a distributed or stray capacitance of 1 $\mu\mu$f appearing between ground and the lead from the coupling capacitor to the grid of tube V2. The stray capacitance

AT.144

Figure 9-7.—Capacitance at high frequencies.

C_d effectively shunts the 5,000-ohm grid impedance Zg. If an RF signal at a frequency of 2 MHz is traveling from the tank circuit of V1 to the grid of V2, the 1 $\mu\mu$f distributed capacitance offers a capacitive reactance of 79,618 ohms to the signal. This value is so high in relation to Zg that its effect is negligible at this frequency and similar low frequencies. If, however, a 100 MHz signal voltage is coming from the tank circuit of V1, the same 1 $\mu\mu$f stray capacitance offers only 1,592 ohms of capacitance reactance.

Now the signal voltage sees a relatively low impedance path across the stray capacitance, offering less than one-third the opposition of the grid impedance Zg. Therefore, more than two-thirds of the signal voltage is shunted across this path and lost. If the frequency of the signal voltage is increased to 400 MHz, the reactance drops to 398 ohms, and only a very small amount of the signal voltage reaches the grid impedance.

To keep the stray capacitance at a minimum, the circuit wiring is kept well spaced with short leads that run at right angles to one another whenever possible.

DESIRABLE EFFECTS.–For certain applications, such as IF amplification, a parallel LC (inductance-capacitance) circuit, resonant at a single frequency, is useful. A simple way of achieving this is to wind a coil in such a manner that the total (distributed and stray) capacitance is used to make the coil self-resonant at the desired frequency.

12398

Part (A) of figure 9-8 shows the distributed capacitance that exists because of the difference of potential between adjacent turns of any coil. The sum of these small values is shown in part (B) as an effective value of capacitance in parallel with the lumped inductance of the coil. Although most inductors are wound to minimize the distributed capacitance, some are designed to offer the necessary capacitance to provide a desired L/C ratio. This offers an advantage because the response of the tuned circuit can be made sharper than would be possible with lumped-property coils and capacitors.

Resistance

The term "distributed resistance" seldom is used, because it is necessary to distinguish between the resistance offered to d.c. and low frequency a.c. and the resistance offered to RF currents at the higher frequencies.

Depending on the conductivity of the metal or alloy, all conductors have d-c resistance.

Figure 9-8.–Parallel self-resonance.

It is distributed uniformly along conductors that are uniform in cross sectional area, shape, and conductivity. Resistance to RF, however, is caused by d-c resistance plus the effect of self-inductance, which is greater at the center of a conductor than at the surface. At the lower frequencies, this self-inductance has little effect on the flow of current because the values of inductive reactance are extremely small. As the operating frequency increases, the inductive reactance at the center of the conductor becomes higher, and the current seeks the lower reactance path toward the surface, resulting in a current distribution that is not uniform.

This tendency of the current to flow on or near the surface of a conductor is called SKIN EFFECT. As the frequency increases, less current flows in the center of the conductor and more flows on the surface. The result is that more current is forced through less conductor material, with higher losses and more heating. Because the center of the conductor is not carrying current, the effect is the same as using a smaller conductor. The RF resistance at higher frequencies can amount to several times the d-c resistance of the same conductor.

MINIMIZING SKIN EFFECT.–Skin effect takes place regardless of the shape of the conductor, but it causes less RF resistance in conductors having rectangular cross sections than in those that are circular. Flat copper strips are sometimes used, but are more expensive and not easy to work.

Litz wire, as it commonly is called, is made up of many strands of very fine enameled wire woven together. The current is divided among the strands, and the skin effect on any single conductor is extremely small. Litz wire is comparatively expensive, however, and is not widely used.

Probably the best method of avoiding losses from RF resistance is by silver plating the conductors. This does not eliminate skin effect, but takes advantage of it. When the plated conductor carries RF current, skin effect takes place as usual. Now however, the current is flowing in the silver plating, which has less d-c resistance than ordinary conductors; therefore, the RF resistance is reduced considerably. In practice, plating is expensive, limiting its use.

13399

OBJECTIVE:

To learn to use the 30°/60° and 45° triangles.

RELATED INFORMATION:

Triangles commonly used in the field of drafting are the 8-inch 45° triangle and the 10-inch 30/60° triangle (Fig. 1). They are used for drawing vertical lines. This use and other uses are shown in Fig. 2. To draw vertical lines, set the triangles against the T-square with the perpendicular edge nearest the head of the square and thus toward the light. These lines are always drawn upward from bottom to top. Triangles are used even more, perhaps, than the T-square; therefore you should constantly practice using them until you have mastered the technique required for their correct use.

FIG. 1

FIG. 2

1337 4c 1331

The most common means of reducing RF resistance is to use a hollow conductor or one of larger diameter. Again, this does not eliminate skin effect. The depth to which the current penetrates is affected only by the frequency and the conductor material; consequently, when the diameter is increased, the current layer has the same thickness but more cross sectional area in which to flow. This reduces the effective RF resistance.

Electrical Losses

As the frequency of operation is raised, the electrical loss in lumped property components increases until a frequency is reached beyond which this increasing loss cannot be tolerated. The increasing loss is, in reality, a combination of three distinct effects–dielectric loss, RF resistance, and radiation loss.

Even in the best dielectric materials, losses increase with frequency. A definite amount of applied energy is lost in each cycle; the more cycles occurring in a specified time, the greater the amount of heat generated in the dielectric.

The RF resistance loss increases with frequency because of increased skin effect.

Radiation loss occurs in any RF circuit. This loss results from direct radiation of energy from individual parts. As long as the circuit element is not more than about one-tenth of a wavelength in any physical dimension, the radiation loss is usually negligble. With increasing frequency, however, it eventually becomes impossible to scale down the physical size of components in proportion to the decrease in wavelength. Losses from radiation increase thereafter. The addition of RF shielding around the circuit decreases the radiation loss, but causes energy to be lost in heating the shield.

The increasing losses which result from increasing frequency reduce circuit efficiency. This factor makes it desirable to use circuit elements and arrangements which have lower built-in losses. As yet it has not been possible to construct lumped property components which do not have some amount of the other properties distributed within them. Increasing the frequency increases the effects of these distributed properties, resulting in increased electrical losses and decreased circuit efficiency.

It has been found practical, however, to take advantage of the stray and distributed properties. Circuit elements and configurations have been designed for operation at high frequencies, using the stray and distributed properties to supplement or to replace lumped components. At the same time, these configurations are designed to decrease the total electrical losses of the circuit. The operating efficiency of these circuits may be greater than that of equivalent circuits using lumped components.

Vacuum Tubes

Although the basic principles of vacuum tube operation remain unchanged, some factors which could be disregarded at low frequencies become important in tube operation at high frequencies. The inductance of electrodes and their leads and the capacitances between electrodes are quite small in absolute value, but at high frequencies their reactances become significant. Skin effect in the electrodes and their leads increases the RF resistance with increases in frequency. Some power is lost due to direct radiation from the electrodes and their leads. Dielectric losses in the insulating electrode supports are also increased. In addition, electrons do not travel instantaneously from cathode to plate, but require TRANSIT TIME. Transit time produces a phase difference between the cathode and plate signals. At sufficiently high frequencies, this phasing can be a considerable portion of a cycle at the operating frequency.

The overall effect of these factors is to reduce tube operating efficiency as the operating frequency is progressively increased. The factors are always present in a vacuum tube, regardless of the operating frequency. As frequency is increased the effects increase and may become so large that they place an upper limit on usable operating frequency. Although it is not necessary to learn new operating principles, it is important to understand the effects of frequency on the operation of tubes and their associated circuits.

CONSTRUCTION FACTORS.–As the wavelength is made shorter, it becomes comparable in length to the physical length and spacing of tube electrodes and leads. The apparent solution to this difficulty is to scale down the entire

ADA213400

tube structure. There is a practical limit, however, governed by the power handling capacity required. New tube designs have been developed that successfully overcome one or more of the limitations without requiring a drastic size reduction. For further details on tube design, review chapter 1 of Basic Electronics.

When the tube is cold, the dielectric between electrodes is mostly vacuum. In operation this vacuum is partially filled with a stream of electrons, producing a change in the dielectric constant. The dielectric constant, and therefore the interelectrode capacitance of the tube, changes with variations in the electron stream. The normal capacitance values are measurable, and are listed in tube characteristics tables.

Not only does interelectrode capacitance limit the frequency by establishing a minimum value below which it is impossible to go, but it also varies with the applied voltages and with the loading of the oscillator. This causes frequency instability, particularly when the interelectrode capacitance forms a large part of the tuning capacitance.

TRANSIT TIME.–The effect of transit time is of special concern in connection with the input impedance of the tube. The signal applied to the grid causes a change in the density of the flow of electrons past the control grid. This in turn, causes a current to be induced into the grid. The induced grid current may flow either into or out of the grid, depending on the relative grid voltage at the time. Part of the current flowing in the grid is the current which charges the grid to plate capacitance. The voltage which produces this current is the vector sum of the input voltage (grid to cathode) and the output voltage (across the plate load).

Grid current may flow absorbing power from the input signal, even though the grid is always negative. It has the same effect as if a shunt resistance and a shunt capacitance were connected across the grid and cathode terminals of the tube. The loss of signal energy brought about in this manner is the most important effect of transit time, and the loss increases as the frequency increases.

At lower frequencies with a resistive load, the input and output voltages are (for practical purposes) 180° out of phase and add algebraically to determine the charging current for the grid to plate capacitor. This current is 90° out of phase with the input voltage. At higher frequencies, where transit time is an important factor, the plate current lags appreciably behind the input voltage. At these frequencies, the plate voltage is less than 180° out of phase with the input voltage, and the voltage across the capacitor lags the input voltage slightly. As a result, the charging current is no longer 90° out of phase, but now has an in-phase component. The in-phase current results in power being consumed in the grid circuit. The consumption of power is effectively the same as adding a high resistance between the grid and cathode, with the resistance decreasing as the frequency is increased.

Transit time effects can be minimized by scalling down tube dimensions or by increasing operating voltages. Amplifiers designed for use above 30 MHz usually have close interelectrode spacing. Many transmitting tube types are very small in proportion to their power ratings, and require cooling by forced air draft.

Screen grid tube types have naturally shorter transit time than triodes, and are used in many equipments to reduce transit time effects.

MISCELLANEOUS EFFECTS.–Other effects on electron tubes at the higher frequencies are caused by grid gas current, grid emission, and heat radiation.

In any electron tube there are always some molecules of gas, because it is impossible to produce a perfect vacuum. When electrons collide with these molecules, positive ions are created and are attracted to the negative control grid. This causes a grid current to flow when the grid is negative. The grid current thus produced is small but has the effect of making the grid less negative, which is undesirable in view of the effects of input resistance in this frequency range.

Any metal emits electrons if heated sufficiently, although some are much more efficient in this respect than others. In miniature tubes suitable for use at frequencies higher than 30 MHz, the grid is heated because of its nearness to the cathode as well as by the in-phase grid currents. Some electrons strike the grid even though it is negative, with the possibility

of secondary emission. As a result, there is a possibility of both primary and secondary emissions from the grid. This adds to the space charge and is undesirable because it varies erratically.

FREQUENCY BANDS

The radiofrequency portion of the electromagnetic spectrum(designated "Hertzian waves" in figure 9-3) extends from approximately 30 kHz to approximately 3,000 GHz. As previously discussed, both propagated and nonpropagated waves exhibit characteristics which depend on frequency. As a matter of convenience, this part of the spectrum is broken down into "bands" of frequencies. Peculiar characteristics of radio waves are then described in terms of the frequency bands in which they occur.

It must be remembered that there is no sharp division between frequencies at which these changes occur. Rather, the changes occur gradually, becoming more or less pronounced as the operating frequency shifts in one direction or the other. When a peculiarity is attributed to a band of frequencies, the designated limits of the band should be considered as falling somewhere near the center of a transitional range of frequencies through which the change occurs.

As an example of the previous statement, the upper limit at which radio signals can be returned effectively to the earth's surface from the ionosphere is considered to be about 30 MHz. For this reason 30 MHz was chosen as the lower frequency limit of the VHF band (fig. 9-3); HF and lower frequencies are considered capable of reflection, while all higher frequencies are considered limited to direct transmission (line of sight). In actual practice, this 30-MHz dividing line is not an abrupt one. There is no abrupt change in the ability of the ionosphere to return waves to the earth as the operating frequency is increased or decreased. The change in the behavior of the ionosphere takes place over a wide region of the frequency spectrum, with the region centering about 30 MHz. The point of highest reflectible frequency may be considerably higher or lower at any given time under given conditions.

The 300-MHz dividing line between the VHF and UHF bands and the 3,000-MHz upper limit of the UHF band are also more or less arbitrary figures, agreed upon for convenience. They do not represent sharp divisions, but rather as the approximate center point of transitional region.

Transmitters and receivers installed in naval aircraft are frequently classified as VHF or UHF equipment. In practice, these equipments usually cover only a portion of the designated band. VHF equipments normally cover frequencies between 115 and 156 MHz. UHF equipments usually operate from 225 to 400 MHz. Although this frequency range includes the upper portion of the VHF band, the equipments are designated as UHF.

CHARACTERISTICS OF VHF AND UHF

The outstanding characteristic of propagated waves in the VHF and UHF bands is its line-of-sight limitation. As previously stated, these frequencies are not usually returned to earth from the ionosphere. Even in the VHF band, however, sporadic ionospheric reflections occasionally permit long-range use of these waves. Since sporadic conditions are not consistent and predictable, ordinary usage of this band is limited to line-of-sight operations.

The outstanding characteristics of electronic equipment designed to operate in these bands are noted in the size of components and in the use of stray and distributed properties of L, C, and R to supplement the properties of lumped components.

In VHF equipments, the L, C, and R are usually lumped components. Due to the frequencies involved, the required values of L and C are smaller than those required at lower frequencies. This factor permits use of inductors which consist of only a few turns of wire—the high frequency permits even this small value of inductance to produce the high reactance required. The high frequency also permits use of capacitors with smaller plate areas.

In circuit design the stray and distributed properties of L and C and the a-c resistance are taken into consideration, and these factors are then used to supplement the lumped values. In maintenance procedures, it is important to avoid excessive movement of components or wiring, since this movement affects the stray inductance and capacitance of the circuit.

The use of small series resistors to suppress parasitic oscillation (undesired resonance within a stage due to the effects of stray

L and C) is common in VHF and UHF equipment. Also common in these circuits is the use of coiled interconnecting leads to introduce inductance into d-c and low frequency a-c signal paths. With normal operating conditions, this small inductance has neglible effect, so signal characteristics are not affected. High frequency signals are, however, present within the equipment, and these signals are coupled (through stray L and C) into low-frequency leads. The large inductive reactance which is produced by these signals prevents the introduction of large magnitudes of high frequency signals into the low frequency circuit.

Tubes used in VHF equipment are usually of the miniature or subminiature type, to take advantage of the low interelectrode capacitance and decreased transit time.

Components used in UHF circuits carry the same efforts even further. Parasitic suppression is accomplished in the same manner as in VHF circuits. Frequent use of series inductors and shunt capacitors in d-c leads is an additional filtering method designed to keep RF signals out of the d-c supply. In many circuits the lumped L and C components are completely eliminated, and resonance is achieved through distributed and stray values alone. Where "lumped" components are still used, they often consist of a looped wire–a half-turn "coil" may comprise the resonant tank.

Hollow (tubular) conductors, mounted parallel to each other and connected by a sliding capacitor or shorting bar (for tuning) are frequently used as the resonant tank in medium and high power oscillators and amplifiers. Other such stages make use of special tubes built with the tube elements internally connected to concentric cylinders.

Transmission lines for VHF and UHF equipment are usually coaxial cables, but in the upper part of the UHF range, some use is made of waveguide.

MICROWAVE CHARACTERISTICS

Microwave circuits are characterized by the almost complete absence of lumped inductance and capacitance; maximum use is made of the distributed propeties of conductors. Tank circuits usually consist of resonant cavities, with klystrons and magnetrons supplying the required power. The transmission line is almost invariably waveguide in high power circuits, although coaxial cable is sometimes used to transfer low signal magnitudes.

Within the microwave circuit, signal transfer is usually accomplished in the form of electromagnetic waves rather than as voltage or current variations. This method of signal transfer practically eliminates the effect of a-c resistance, which could be excessive at these frequencies.

Input and output impedances and the selection of alternate signal paths are controlled by the use of waveguide sections. These sections are built or adjusted to the proper length so as to supply the desired impedance, from open circuit to short circuit. By selecting specific methods of coupling or by changing the contours of the inside of the waveguide, it is possible to control signal magnitudes and to determine the reactive component of the signal.

The basic components of microwave systems are discussed individually in chapter 11 of this manual. Brief discussions of the overall operation of specific microwave systems appear in chapter 18.

MICROELECTRONICS

The Naval Air Systems Command uses the term MICROELECTRONICS to refer to those processes and techniques involved in the construction of circuits in a relatively small, nonseparable form. Active elements such as transistors, and passive elements such as resistors and capacitors are closely integrated on a single wafer or block to form a functional circuit.

Microelectronics includes the construction technique referred to as integrated circuitry; it also includes the use of thin-film techniques; and, in some cases, it includes the use of discrete microcomponents (for example, a transistor made separately and then added to an assembled unit). The term is not used to include construction using miniature (but otherwise conventional components with interconnecting wiring between the individual components, even though some wiring may be required between assemblies in microelectric construction.

MICROMINIATURIZATION, on the other hand, is a term generally having a broader meaning. This term is used to refer to all efforts directed toward making electronic devices as small as possible. The Army's micromodular construction technique, for example, is excluded from the NavAir concept of microelectronics, although it represents a good example of microminiaturization. The micromodule consists of tiny wafers of insulating material, on each of which is mounted an electronic element such as a diode, capacitor, transistor or resistor. These elements, some the size of pinheads, are connected by wire threads. Micromodules represent the last practical step in the process of miniaturizing conventional electronic devices. Hundreds of thousands of such elements can be crammed into a cubic foot of space. Microelectronic devices are even smaller than micromodules.

PURPOSES OF MINIATURIZATION

In conventional circuits, electrical connections are the cause of numerous failures. As electronic systems become more complex, the increase in the number of parts used and of the connections between them decreases the potential reliability of the circuitry. A characteristic of microelectronic devices which is even more important than their small size is the drastic reduction in the number of soldered connections required. Using a single block of semiconductor material, it is possible to fabricate complete functional subassemblies which require connections only for inputs and outputs from the assembly.

The major objective of the microelectronics trend is to develop building blocks, with each block capable of performing the function of a complete circuit or group of circuits. With this capability, the block should then have one or more of the following characteristics:

1. Perform more electronic functions per unit of volume, weight, cost, power input, and power dissipated than is possible with even the most advanced components and circuit assembly techniques currently available.
2. Possess considerably higher reliability than their conventional counterparts.
3. Require a minimum of maintenance as a result of improved reliability.
4. Achieve low unit cost, making throwaway maintenance practices economically practicable.
5. Perform certain new functions which are not possible with presently available components.

Size reduction alone is not always the aim of microelectronics; small size is inherent in the technology. Although the size and weight reductions are highly significant, in some applications they do not justify the development of an entirely new system of fabrication.

Trouble isolation to a module rather than a specific component part reduces the number of items to be checked, and thus decreases maintenance time. The requirement of increased reliability at reduced cost is inherent in this form of maintenance. By mechanizing production and improving processing techniques, the initial cost can be drastically reduced; by automatic system checkout techniques, trouble isolation can be made almost completely automatic.

CLASSES OF COMPONENTS

The conventional circuit with normal or miniature components will continue to be used. Some components such as the magnetron and high power-consuming devices do not, at present, lend themselves to drastic size reduction. Miniature components, although they do not compare with thin-film or solidstate integrated circuitry in size reduction, will also continue to be used in military applications. Unfortunately, only a limited selection of miniature components, modules, and packaged assemblies is available. It is estimated that 25 to 30 percent of all military needs for electronic circuits will continue to be filled for years to come by normal or miniature components.

This discussion describes the various classes of microminiature components now being used, reviews a few of the present applications, and notes some of the problems yet to be solved in the microelectronic techniques.

Discrete Components

In reducing weight and bulk, the microminiature component goes one step farther than the miniature component. Capacitors, resistors,

transistors, and diodes are currently being used in conjunction with passive thin films. By micropackaging techniques, size and weight reduction is realized, but the connection into usable circuits is a time-consuming and tedious operation, and the soldered connections do not realize full reliability potential.

Hybrid Circuits

Hybrid circuits using thin-film subassemblies of passive elements to which the active elements are attached represent the next logical step in fabrication. The number of soldered connections is reduced and the number of wafers is also decreased. Thus, this method is a slightly improved example of microminiaturization which is sometimes included in the definition of microelectronics.

Thin-Film Devices

Thin-film microelectronic devices consist of passive elements (currently limited to resistors, capacitors, and small inductors) on substrates of glass, ceramic, steatite, or other suitable insulating material. All active elements, and some passive elements, are added to the circuit as discrete components.

Solidstate Integrated Circuits

Solidstate integrated circuits represent an extension of silicon transistor technology. These circuits derive their name from the fact that the circuit is formed in a single block of silicon semiconductor material. They contain both active and passive circuit elements interconnected with deposited metal patterns. The selection of circuits fabricated on the solidstate principle is at present the limiting factor in utilization of the solidstate module. Considerable development emphasis is being given to this limiting factor.

TECHNIQUES

There is a difference between microelectronics and micropackaging. The latter generally refers to the assembly of discrete, miniaturized components within a single enclosure and electrically connected by wires and deposited films. This technique is similar to conventional methods in that separate, discrete components are used. The individual component cases or enclosures may, however, be removed and the individual components bonded to a common substrate and interconnected, with the complete subassembly then hermetically sealed in a single package. The individual components must be individually processed, handled, and interconnected. This decreases the reliability of the assembly, and increases the unit cost. It does, however, approach the size and weight reduction of microelectronic circuits.

In the true microelectronic technology, all the equivalent components (active and passive) are fabricated in one continuous operation on an entire block of material. The components need never be handled as individual items, and all connections except input to and output from the circuit are an integral part of the block. This technique maximizes reliability because of the lack of separate interconnections within the individual module. Computer-controlled automatic processing techniques will standardize construction and reduce unit cost of producing the modules, making throwaway maintenance economically practicable.

Actual production and manufacturing techniques presently in use are summarized briefly in the following paragraphs.

Deposited Film Technique

This technique involves the fabrication of circuits which are composed of thin films of metallic or semiconductor material deposited on substrates. The individual elements of these circuits cannot be disconnected from each other.

Several methods are used to deposit the film. The most commonly used method consists of evaporating a metallic or dielectric material in a high vacuum and condensing the vapor onto a thin inactive wafer. Carefully prepared masks control the areas exposed for deposition. By successive steps of depositing metallic or dielectric films, resistors, capacitors, and conductors can be deposited onto a single wafer. (Note that reference is made to the conventional types of components as used in the part. The differences are that there are no leads between components, and

that circuit interconnections are an inherent part of the process.)

Other methods used to deposit the film include the oxidation of certain metals, thermal decomposition of gaseous compounds, and "sputtering." In the oxidation process, the metal is first deposited onto the substrate, and a specified section is then oxidized to obtain special characteristics. In thermal decomposition, extremely close tolerances are required in the masking, purity of the compound, temperature, and exposure time.

Some materials have extremely high melting temperatures and are therefore almost impossible to deposit by the evaporation technique. For these materials, the sputtering technique has been developed. In this process, the material is boiled under extreme heat in a high vacuum, and then deposited in small droplets onto the substrate wafer.

Silk Screen Technique

In this process, a mixture of special sand and fluxes is applied to a ceramic substrate and then the unit is fired (in a manner similar to the ceramic painting and glazing process). Prior to firing, interconnections are screened on, using metallic "inks"; external connections are welded, brazed, wire-bonded, or soldered after firing. Use of the silk screen technique results in a film of considerably greater thickness than that of the thin-film technique.

Semiconductor Growth

This technique is the one most commonly used in the production of solidstate circuits. The process begins with a single bulk-form block of semiconductor material as the substrate. Impurities are alloyed or diffused into the material to form PN junctions. (The semiconductor material itself is used in the formation of resistors and capacitors.)

In most cases the elements themselves and their interconnections are integral parts of the semiconductor substrate; differentiation between the elements and the substrate becomes vague. Internal interconnections are reduced by designing one element to begin where another ends.

MANUFACTURING PROCESS. –The manufacturing process consists of a number of steps using silicon dioxide masks to control the doping of the semiconductor material. By use of computer-controlled equipment, the original block of semiconductor material is progressively masked, doped, oxidized, etched, and otherwise processed to form junctions which possess the desired characteristics. Thus a single block of material may contain the equivalent of various combinations of transistors, diodes, resistors, capacitors, and interconnecting wires, with areas provided for connecting leads for input signals, power, and output signals.

CHARACTERISTICS. –The performance of solidstate circuits is limited by the capacitance of the back-biased junctions between the silicon substrate and the N-type islands in which the circuit elements are diffused. This parasitic capacitance has been a limiting factor in obtaining good high frequency response.

Resistance and capacitance values are somewhat more limited in solidstate circuits than they are in thin-film networks, and inductance is as yet unattainable. Circuit resistor tolerances of closer than 20 percent are difficult to attain. Temperature coefficients are relatively large for all components. Capacitors have low values of Q, are polarity-restrictive, and have comparatively low voltage breakdown values.

The absence of interconnections in completely integrated circuits should lead to greatly improved reliability, simplified maintenance practices, and shorter "downtime" losses.

Power capabilities are limited by the drift in circuit characteristics caused by internally generated circuit heat. Power dissipation is therefore greatly restricted.

APPLICATIONS

Microminiaturized and microelectronic circuits and components are appearing in virtually all new equipments. It is expected that microcomponents and microcircuits will eventually replace about 75 percent of those in present use. However, there are some specific applications especially well suited for their usage.

13406 CONFIDENTIAL

In chapters (15 through 20) numerous equipments are discussed. Many of these equipments indicate that the module is the basic functional unit, or that the module is the smallest maintainable item. Equipments involved in automatic data processing, logical computations, sequential switching, or precise navigation are currently being designed as integral parts of an overall weapon system—and they are being designed with microcircuit techniques. Another area particularly well suited for miniature and microcircuits is the survival transceiver packed in the liferaft of ejections seats.

PRINTED CIRCUITS

This type circuit appears more and more in electronic equipment, and has proven itself to be equal in operation to conventional type construction. A few simple machine operations automatically produce circuits that formerly required a production line of workers performing the same jobs by hand.

One method of manufacturing a printed circuit is the "photoetching" process. A plastic or phenolic sheet with a thin layer of copper coating may be used. The copper coating is covered with a light-sensitive enamel, and a template of the circuit that will ultimately appear on the plastic sheet is placed over it. The entire sheet is then exposed to light. The area of the copper that is exposed reacts to the light. This area is then removed by an etching process. The exposure of the printed circuit is similar to a photographic exposure. The enamel on the unexposed circuit protects the unexposed copper from the etching bath that removes the exposed copper. After the etching bath, the enamel is removed from the printed circuit. This leaves the surfaces in a condition for soldering parts and connections.

BOOK CIRCUITS

Figure 9-9 shows an improved type of construction, from the troubleshooter's standpoint, consisting of a removable subassembly of the type called "books." These books are readily removable and have numerous internal and external test points to facilitate troubleshooting. The books are built of easily replaceable standard parts. Most test racks have plug extensions

AT.146

Figure 9-9.—Electronic "book" construction.

that permit any book to be raised, making all parts accessible for checking and repairing. The book is not expendable, but can be easily repaired since all parts are of conventional design. Miniature and subminiature parts are so common in today's electronic equipment that they are now considered to be conventional.

DOPPLER PRINCIPLE

The topics of waves and motion were discussed separately in chapter 5 of this manual. The Doppler principle involves the effect of motion on a wave which has been generated and propagated. This effect is based on the fact that all waves, once they have been propagated into space or into a conducting medium, travel at a velocity which is independent of the wave source. The effect was first noted in connection with sound waves; it has subsequently been observed throughout the entire frequency spectrum. In all cases, a shift in the apparent frequency occurs when the wave source and the detector move toward or away

BOOK 1348[illegible]

from each other. If the distance separating the source and the detector remains constant, no frequency shift occurs. The present discussion is limited to the implications of this principle in electronic applications.

PRINCIPLE

For this discussion, assume that a wave source is moving in the direction of its propagation. As the source moves, it partially overtakes one wave front before the next is emitted. This has the apparent effect of decreasing the distance between corresponding points on successive waves. (The speed of wave travel is independent of the motion of the source, and need not be considered in the discussion.) The wavelength (as the waves reach a stationary detector located ahead of the source) is shorter than the original frequency would indicate; the detector apparently receives a frequency higher than that propagated. If the source moves in a direction opposite to the direction of propagation, the frequency is decreased in a corresponding manner.

The same effect is noted in the case of a stationary source and a moving detector. In this case, the detector is overtaking part of the wave front, and the time and wavelengths are shortened, and the frequency is apparently increased.

THEORY

This discussion of the Doppler principle is somewhat simplified in order to present the fundamental theory involved. In the explanation that follows, three aspects of a given radar beam are discussed. These are the generated signal wave, the incident wave, and the received wave. The timing of the wave is discussed and illustrated to show how phase shift and frequency shift occur.

An examination of one microsecond of the signal radiated from a CW radar transmitter shows that the signal is composed of many cycles of RF energy. In the time of 1 microsecond, a radar that operates at 13.3 GHz will radiate 13,300 cycles of RF energy, only a few of which are shown in figure 9-10 (A). Each cycle occupies a definite period of time and has a definite physical wavelength. At the frequency mentioned, each cycle occupies 75 micromicroseconds and has a phsycial wavelength of 22.5 millimeters. An expanded view of one cycle of RF energy at 13.3 GHz is shown in (B) of the figure. This cycle will later be shown with one cycle of incident signal superimposed on it to demonstrate expansion due to Doppler effect.

At this point two approaches to explain the effect of signal expansion are used; one involves the action of a cycle of energy as it leaves the antenna, and the other considers the shape of each cycle to be an arc of wave energy. First, consider a single cycle as it leaves the antenna.

The cycle shown in figure 9-10 (B) occupies a certain discrete distance in space and is, in fact, the wavelength of the signal at the frequency shown. When transmitted from a stationary antenna, the leading edge will move out into space 22.5 millimeters by the time the trailing edge leaves the antenna. However, if that cycle is emitted from an antenna pointed aft from a moving aircraft, then the antenna will move a small distance during the time that the cycle is being transmitted. The trailing edge will, therefore, be a greater distance away from the leading edge than it was when the cycle was transmitted from the stationary antenna. This is expansion.

AT.147

Figure 9-10.–Examination of a pulse.

Figure 9-11 illustrates this effect and shows, by the dotted line, the space that a cycle would have occupied had the antenna been stationary. Inasmuch as the cycle has been expanded, it occupies more distance in space, the wavelength has been increased, and the frequency has been proportionately decreased. The difference in frequency for this first Doppler shift is proportional to the sine of the radar beam angle multiplied by the ratio of the aircraft velocity to the generated wavelength. In symbols, this would be

$$D.s. = \frac{V}{\lambda} x \sin \phi$$

When the signal is reflected from the ground and returns to the antenna, a similar expansion occurs. A slightly longer time is required for the cycle to reenter the moving antenna than that would be required if the antenna were stationary. Thus, a double expansion has occurred. This double frequency expansion can be measured by the formula.

$$D.s = \frac{2V}{\lambda} x \sin \phi$$

The change in frequency is slight, but measurable, and is a direct indication of the speed of the aircraft.

Compression of the signal will result if the antenna is pointed in the forward direction. The explanation is similar to that of expansion except that the leading and trailing edges of the cycle will be closer together (cycle compressed). The effect will be to shorten the wavelength and increase the frequency.

Another approach to compression and expansion is to consider that a CW signal consists of waves of energy radiated from the antenna. Figure 9-12 illustrates the spacing between the waves of a signal from both stationary and moving antennas. The effect is the same as that previously described. The increased spacing (wavelength) between adjacent waves of energy is a direct indication of frequency change. The received signal frequency, when mixed with the generated signal frequency, produces a difference frequency which falls in the audio spectrum. This audio-frequency is a direct indication of the aircraft's speed.

Several specific equipments which make use of the Doppler principle are discussed in some detail in chapter 17 of this manual.

MASERS AND LASERS

The maser (Microwave Amplification by Stimulated Emission of Radiation) is an impor-

AT.148

Figure 9-11.–One cycle expansion.

Use caution in their care and upkeep and avoid denting or dropping them, for this will hinder the drawing of straight lines. Keep them clean with a good cleaning agent.

QUESTIONS:

1. Why must the triangle be placed perpendicular against the T-square?
2. Which two triangles are most commonly used?
3. Why keep triangles clean?
4. Can both the 30°/60° and 45° triangles be used for drawing vertical lines?
5. How would you clean a triangle?

ASSIGNMENT:

Draw a $\frac{1}{2}$-inch border all around the buff paper issued to you. Proceed to draw the lines as shown, using your T-square and triangles.

AT.149

Figure 9-12.–Energy wave spacing.

tant member of the rapidly growing family of quantum electronic devides. The optical maser, or laser, operates in the visible and near infrared portion of the electromagnetic spectrum.

The feasibility of an optical maser was first suggested in 1958. The first operating laboratory model was constructed in 1960, less than 2 years later. Research, development and application of the laser are currently proceeding at a pace exceeding that of any other device in the history of electronics.

THEORY OF OPERATION

The generation of coherent radiation in the visible region of the electromagnetic spectrum involves interaction of radiation and matter. (See fig. 9-13.) Electromagnetic energy is always absorbed or emitted by an ion or atom in discrete units (photons). For radiation at a given frequency, all photons emitted have energy equal to the product of hf, where $h = 6.624 \times 10^{-27}$ erg sec is Planck's constant, and f = frequency.

A given ion (or atom) can make the transition to a higher energy level by absorbing a photon from the electromagnetic field. It can make a transition to a lower level in either of two ways: spontaneous emission (a random process), or stimulated emission (a coherent process–the phase of the impinging wave is retained in both time and space).

When radiation of the proper frequency enters an area containing ions in thermal equilibrium, it will strike an ion. The ion struck will, if at the upper energy level, transfer to the lower energy level by stimulated emission; but if it is at the lower energy level, it will transfer to the upper level via absorption. Since under equilibrium conditions (fig. 9-14) there are always more ions at the lower energy level than at the higher level, the overall net effect is absorption. If it were possible, however, to begin the operation with more ions in the high energy state than in the low energy state, the reverse would be true. Then entering electromagnetic energy of the correct frequency would cause net stimulated emission, radiation.

Several different techniques for producing population inversion are employed. The method commonly used in solid state lasers is described in terms of ruby, an aluminum oxide containing chromium. The energy levels responsible for the absorption process are shown in figure 9-14. An ion in state 1 absorbs green light and goes to state 3. It rapidly gives up energy in the form of heat and drops to state 2. The mean time that the ion remains at the metastable level, state 2, is on the order of 1 millisecond (about 200 times as long as at state 3); then it spontaneously returns to the ground level by emitting a particular frequency in the red region of the spectrum. If the crystal is illuminated with sufficient green light of the correct wavelength, the population inversion can be maintained. This illumination is commonly termed "pumping."

If the material is properly selected and sufficiently pure, the stimulated emission can be limited to specific frequencies; i.e., frequencies that are known and determined by the physical properties of the elements involved.

LASER OPERATION

The active ion makes a transition from the ground energy level to the pump level when it absorbs energy from the pump sorce. The ideal pump source would emit photons of only the de-

13410

AT.150

Figure 9-13.–Spectral range of sources of electromagnetic waves.

sired energy (frequency); however, since such sources are rarely available, it is usually necessary to compromise and use white light. This pump energy could be focused on the laser by sunlight, electronic flashtube, or any other sufficiently intense course.

The ion rapidly falls from the unstable pump band to the metastable level by a photon transition. The metastable level tends to become heavily populated if the pump rate is sufficiently high to put ions into the metastable state faster than they drop back to ground state by spontaneous emission.

After slightly more than half of the ions have been pumped from the ground state to the metastable state (several hundred microseconds for a typical ruby laser), any spontaneously generated light at the correct frequency

$(f = \frac{h}{E})$, corresponding to the energy difference

between the ground and metastable energy levels, will cause net stimulated emission. The device will generate coherent electromagnetic energy, coherent light. Because of the design of the equipment, the light generated will be of a given frequency; will have a fixed phase relationship; and will be radiated, parallel to the longitudinal axis through the lightly silvered end of the laser rod.

PRACTICAL REQUIREMENTS

A practical laser device must meet the following requirements:

1. Select a material (gas or solid) which emits light of the desired frequency and is transparent to that frequency. The first gaseous laser, using a helium-neon mixture, emitted light at a wavelength of 1.15 microns (1.15×10^{-6} meters) or 260 terahertz (2.6×10^{14} Hz). The bandwidth spectrum of the emitted light was about 25 kHz because of frequency-pulling caused by mechanical vibration in the structure.

2. Insure adequate purity of the material. Impurities tend to absorb or refract the emitted energy, interfering with the laser action, lowering efficiency and causing unwanted hot-spots.

AT.151

Figure 9-14.–Energy levels of typical laser materials.

3. Encapsulate the selected material to promote optimum efficiency. Proper design insures maximum coupling or pump energy to the laser. Correct dimensioning insures the maximum level of stimulated emission in the desired direction of propagation.

4. Find an efficient pump source, that is, a source which will maintain the desired energy level inversion with the minimum amount of applied energy. This increases efficiency and decreases heat dissipation problems. The ruby laser has two pump frequency bands, centering on 4100 and 5600 angstroms ($1A = 1 \times 10^{-10}$ meter).

The laser shown in figure 9-15 is refined as follows: a highly pure ruby crystal is grown, machined and polished to a right circular cylinder using techniques developed by transistor technologists. One end is polished optically flat and silvered to become completely reflective to visible frequencies. The other end is also polished optically smooth, but is only partially reflective. The crystal is machined to an exact multiple of the wavelength of the desired operating frequency of the laser; the crystal thus acts as a resonant chamber, continuously reflecting energy along the longitudinal axis. The lightly mirrored end will transmit a portion of the energy which strikes normal (perpendicular) to its surface.

The emitted energy can be focused or otherwise treated in the same manner as ordinary light. It differs from normal light in that it is composed of an extremely narrow band of frequencies and it has a definite spatial phase relationship.

AT.152

Figure 9-15.—Simple laser.

APPLICATIONS

It is anticipated that lasers and masers will find extensive applications in many major fields. In view of the known characteristics of masers and lasers, studies are currently conducted to find specific applications in the following fields:

1. Surgical tool. Using a converging lens system, the laser beam can be focused to approach a true point source of light at the focal point. The theoretical limit of the spot diameter would be approximately 1 wavelength (6943 angstroms for the ruby laser). The entire energy radiated could be focused at one spot, creating at that spot a temperature more intense than that at the surface of the sun. This laser beam could be used as a superscalpel, or welding torch, for surgical operations on the human eye and nerves.

2. Communications device. The laser beam can be used as a super-directional communications link in a new uncluttered part of the spectrum. Many researchers are experimenting with methods of modulating the laser beam. One method of modulating the beam with audiofrequencies has already been developed.

3. Energy transfer device. The laser beam constitutes the most intense form of energy propagation yet put at man's disposal. Laboratory models have been used to burn holes through sheet steel. If a sufficiently high-power laser were available, it could radiate sufficient energy from the ground to power satellites or robot helicopters, with practically no energy loss due to transmission.

4. Frequency and distance standard. Since the frequency emitted by a laser depends upon the atomic properties of the material used, the frequency would be known with a high degree of accuracy and would remain constant for the operating life of the laser. The laser will permit all research laboratories to maintain an accurate secondary frequency/distance standard. (1 meter = 1,650,763.73 wavelengths of the orange-red spectral line of krypton 86.)

5. Precision radar system. Lasers have such high spectral purity and directionality that they can be used as precision radar systems. An earth-based laser radar, with an optical system only inches in diameter, has such a high resolution that the beam at the surface of the moon would only be a few miles wide. In a

recent test at the MIT Lincoln Laboratory, the beam of a laser was focused on the moon by a telescope; and returned radiation was detected by a photomultiplier tube after being collected by another telescope. The illuminated area on the surface of the moon was estimated to be 2 miles in diameter.

6. Undersea utilization. Researches are attempting to develop a laser which will operate in the blue-green portion of the visible spectrum. Water is quite transparent at this band of frequencies. A secure undersea communications link or an undersea optical radar has understandably desirable qualities.

In early November 1962, IBM, GE, and Lincoln Laboratory announced simultaneous development of a new laser-a gallium arisinide diode. This new laser has a much higher efficiency potential and far simpler modulation mechanism than its predecessors. It constitutes the next major step forward in laser development. Excited by high current densities (greater than 10,000 amp/cm^2) at its junction, it emits coherent light in the near IR (8400 angstroms) from its polished surface with a beam width on the order of 4 degrees.

The optical laser is destined to become an important segment of the electronics industry. Most high frequency systems (radar, guidance, communications) will employ masers of some type. In the optical region, the laser, only a theory a few years ago, fulfills for the first time the dream of scientists since Newton-a source of coherent light.

13413

CHAPTER 10

ELECTRONIC CIRCUITS

Within any class of electronic equipments there are a large number of identical functions to be performed–and there are usually many different circuit designs used to perform them. Usually no one design is especially better than another. In the interest of standardization, it has been found desirable to concentrate on a few circuit designs for a given function; "preferred circuits" have been selected for standardization and reliability improvement. These circuits have been developed using the latest techniques and fabrication methods. Their use provides maximum flexibility in the performance of specific functions. Economy in parts usage, fabrication costs, and maintenance efforts have been the guiding factors in the adoption of specific circuit designs as the "preferred" circuit.

The preferred circuit configurations and specifications have been made available to all manufacturers of electronic equipment. They are contained in Handbook Preferred Circuits Navy Aeronautical Electronic Equipment, NavWeps 16-1-519 (Series). (Separate volumes are published for vacuum tube and transistorized circuits.) Although use of these circuits is not mandatory in the development of electronic equipments for Navy use, most manufacturers have made extensive use of them.

As a result of the use of these preferred circuits, development of new equipment has become more rapid. Of greater concern to the maintenance technician, however, is the similarity between circuits in different equipments designed to perform identical or similar functions.

Some circuits discussed in this chapter are the standardized preferred circuits. The discussions are necessarily brief; if further information of a general nature concerning a specific type of circuit is needed, Electronics Installation and Maintenance Book, Electronic Circuits, NavShips 0967-000-0120, provides an excellent reference. For the theory of operation of a circuit in a specific equipment, the technical manual applicable to that equipment is recommended.

Several major classes of circuits are not discussed directly in this chapter. Basic Electronics presents basic operating theory of many of these classes. Where that coverage is considered adequate, the circuits are omitted from this discussion.

GENERATING CIRCUITS

Generating circuits, as used in this discussion, refer to those circuits which develop an a-c signal (or a varying d-c level of voltage) as a result of circuit operating characteristics. Signals are broadly classifiable as sinusoidal or nonsinusoidal. Nonsinusoidal signals include square waves, sawtooth waves, pulses, and miscellaneous other types.

Sinusoidal waveform generators comprise the class of electronic circuits called oscillators. A basic discussion of the main types of oscillators is presented in Basic Electronics.

MULTIVIBRATORS

Multivibrators are normally classified as a form of relaxation oscillator. Three basic types are used–astable (free-running), monostable (one-shot), and bistable (flip-flop). The electron tube and transistorized versions of all three types are discussed briefly in Basic Electronics. In the present discussion, three actual circuits are discussed. The first circuit

13414

is the preferred electron tube astable multivibrator; the second is the preferred transistorized monostable multivibrator; third is the Schmitt trigger circuit used in many equipments. The Schmitt circuit discussion compares the electron tube and the transistorized versions of the basic circuit.

Multivibrators may be distinguished as to type by the cross-coupling networks between the plates and grids (or between the collectors and bases). In the astable circuit, the cross-coupling networks provide a-c coupling only; the bistable circuit provides d-c coupling for both sections. In the monostable circuit, only one section provides d-c coupling; the other provides a-c coupling only.

Astable PRF Multivibrator

The astable, plate-to-grid coupled multivibrator shown in figure 10-1 is used as a moderately stable repetition-rate generator. It has greater frequency stability than the blocking oscillator and is more economical of components than the Wien bridge oscillator. One disadvantage of the multivibrator is that the output impedance for positive pulses is essentially equal to the plate-load resistance (which must be relatively high for good frequency stability).

The circuit normally uses a miniature or subminiature twin triode and relatively high values of plate-load resistors.

The speed of transition, as in all multivibrators, depends to some extent upon the capacitance between the tube elements, but no special precaution is required in this circuit. The positive-going transition is retarded by the relatively high plate-load resistance and by the timing capacitance, which shunts the output circuit of the tube during turnoff. The negative-going transition is much faster because it is generated at a lower impedance and is slowed only by the output capacitance of the tube and by stray capacitance shunting the

AT.153

Figure 10-1.–Astable PRF Multivibrator, preferred circuit diagram and waveforms.

13415

plate circuit. The faster, negative-going transition is recommended as a timing waveform.

The total period of a symmetrical, astable multivibrator with grid resistors returned to a positive voltage may be approximately determined from the equation

$$T = (2RC)\ l_n \frac{E_{bb} + E_o}{E_{bb} + E_c}$$

where T = period in seconds

R = value of either grid resistor in ohms (including the active portion of potentiometer R3)

C = value of cross-coupling capac- (C1 or C2) in farads

E_{bb} = voltage to which grid resistors are returned

E_o = voltage drop across either plate resistor when corresponding tube is conducting

E_c = absolute value of grid cutoff voltage with full plate supply voltage on corresponding plate

l_n = natural logarithm (of the fraction)

The frequency stability of a multivibrator is improved by making the timing waveform on the grid of the cutoff tube very large in amplitude and as steep as possible at the time this voltage is approaching the cutoff voltage. In this circuit a large timing waveform is obtained by using a high resistance in the plate circuit. The full voltage drop across this resistor, when the tube is conducting, is applied to the opposite grid as the timing waveform. This waveform is made steeper by returning the grid resistor to a positive voltage instead of to ground. (The exponentially rising voltage on the grid will then be farther from its final value and will be changing more rapidly as it passes through cutoff.)

The equation for pulse repetition period shows the dependence of the repetition frequency on the grid resistors and cross coupling capacitors. When these components vary, the frequency varies slightly. This variation can be compensated for by adjustment of R3. Periodic adjustment of R3 will also compensate for the variation in repetition frequency caused by tube changes. The potentiometer should be readjusted each time the multivibrator tube is changed.

The output-voltage amplitude varies directly as the plate supply voltage. The frequency change caused by variations in the plate supply voltage is in addition to the frequency changes compensated for by R3.

Monostable Multivibrator

Figure 10-2 shows a transistorized monostable multivibrator. The circuit appears symmetrical except for the cross-coupling networks between collectors and bases. Note that C1 permits a-c coupling only between Q1 and Q2, while R6 permits d-c coupling between Q2 and Q1. Notice that C1 has not been assigned a value. As will be shown later, the value of C1 in conjunction with R3 will determine the time delay that can be obtained.

In this circuit, the transistors are PNP types; Q2 is on and Q1 is off. The base of Q2 is connected to -6 volts through R3, providing forward bias for the emitter-base junction of Q2. Q2 remains in saturation in the absence of external signals; thus it has a low resistance, and its collector voltage is nearly 0 volts. The divider network, consisting of R6 and R2 connected to + 6 volts, makes the base of Q1 slightly positive. Its emitter-base junction is reverse biased and it is in the off condition; Q1 appears to have a high resistance. Diode CR2 clamps the collector of Q1 at -6 volts; CR4 clamps the collector of Q2 to -6 volts when Q2 is turned off. Diode CR1 prevents positive noise pulses (which appear on the -18-volt supply line) from being coupled to the base of Q2.

AT.154

Figure 10-2.–Monostable multivibrator.

13416

Under these conditions, then, the input required to turn on Q1 is a negative-going pulse with sufficient amplitude and pulse width to insure its starting. The trigger input network consisting of CR3, C2, and R5 comprises an input gate circuit which discriminates against positive signals and passes negative pulses.

A negative input pulse is differentiated in the input RC network, passes through CR3, and drives the base of Q1 negative with respect to ground. Q1 is now forward biased; and a rapid buildup of Q1 collector current occurs, causing the Q1 collector potential to go from -6 volts toward 0 volts. With Q1 in saturation, the left side of C1 is clamped to ground and a +6 volt step is impressed on the base of Q2, causing Q2 to come out of saturation rapidly.

Q2 collector voltage, however, does not fall abruptly since the associated collector load capacitor must discharge. The negative collector voltage of Q2 is applied to the base of Q1 through the divider consisting of R2 and the C3-R6 network, keeping Q1 on.

C1 then begins to discharge through Q1, the power supply, and R3. The voltage at the base of Q2 is changing exponentially from nearly +6 volts to -6 volts. When the base of Q2 goes slightly negative, Q2 conducts again. Q2 collector voltage rises to 0 volts; and the positive-going waveform is applied to the base of Q1. Q1 is turned off; and C1 charges to -6 volts through R1, CR1, and the emitter-base junction of Q2. The circuit is again in its stable state, awaiting the next input trigger pulse.

Circuit delay time is determined by the off time of Q2. Total delay includes the turnon and turnoff delay times of both Q1 and Q2. For delay intervals greater than about 10 μsec, transistor delay times can be considered negligible. The actual time delay varies with changes in R3 and/or C1. These variations are due to the initial tolerances of the components plus the changes caused by temperature and aging. Therefore, R3 is usually made variable and C1 is selected to have a temperature coefficient equal and opposite that of R3.

Schmitt Trigger Circuit

The Schmitt trigger (fig. 10-3) is a bistable multivibrator. It consists of a two-amplifier regenerative circuit which can stay in either of its two stable states indefinitely. In either state, one amplifier is conducting heavily and the other is cut off. The circuit switches states very rapidly on command. The very fast rise and decay times are useful for triggering other circuits. The circuit can also be used as a gate generator, an amplitude comparator, or a "squaring" circuit.

In the vacuum tube Schmitt circuit (fig. 10-3 (A)), amplifier Ais d-c coupled to the grid of amplifier B and the cathode of amplifier B is d-c coupled to the cathode of amplifier A. Cathode-to-cathode coupling is provided by an unbypassed common resistor.

Figure 10-3 (B) shows the transistorized equivalent of the same Schmitt trigger circuit. An output versus input waveform is illustrated in (C). The output curve shown is based on arbitrary operating limits as discussed in the following paragraphs.

The switching from one state to the other occurs when the input rises to a certain level in one case and when the input falls to a certain level for the other case. The region between the two switching levels or trip points is a backlash or hysteresis region. Note in (C) that the input rises to the upper switching level, causes a switching of states, and then varies considerably but has no switching effect until it falls to the lower switching level. This action is somewhat analogous to driving a gear train which has backlash–the gear train input shaft can be turned back and forth indefinitely and no output shaft movement will occur until the backlash has been taken up.

The loop gain of the circuit determines the width of the hysteresis region. For a loop gain of unity, the hysteresis limits coincide; the circuit switches states each time the input passes the single switching level, regardless of the direction of approach. The no-hysteresis Schmitt circuit is seldom used–slight circuit changes could cause the loop gain to become less than unity. With a loop gain less than unity, both amplifiers of the circuit act as fairly linear amplifiers, and no switching occurs. For hysteresis to exist in the circuit, the loop gain must be greater than unity–the greater the loop gain, the wider the hysteresis region.

AT.155

Figure 10-3.–Schmitt trigger circuits.

BLOCKING OSCILLATORS

The blocking oscillator is another type of relaxation oscillator. It can be free running, synchronized at each cycle or at a submultiple frequency, or it can be driven in the manner of a one-shot multivibrator.

A blocking oscillator is any oscillator which uses the accumulation of a negative charge on the grid capacitor to cut itself off after one or more cycles. Thus, in an oscillator in which the grid swings positive with respect to the cathode, electrons are attracted to the grid and (during charge of the capacitor) accumulate on the plate of the grid capacitor nearest the grid. Since these electrons cannot return to the cathode through the tube during charge of the capacitor, they must return through the grid-to-cathode resistance. If this resistance is sufficiently large, electrons may accumulate on the capacitor faster then they can return to the cathode. A negative charge is thus built up at the grid and may bias the tube beyond cutoff. Once the tube is cut off, no additional electrons are supplied to the grid capacitor. The capacitor then discharges through the resistor, and a point is eventually reached where the tube again conducts. The process is repeated and the tube becomes an intermittent oscillator. The period (rate of the recurrence of operating conditions) is determined by the RC time constant of the grid circuit.

Free-Running

The free-running blocking oscillator is frequently used in radar systems to generate a repetition rate where stability requirements are low. The output can be used as a trigger without additional shaping, but in practice addi-

tional shaping is usually incorporated in conjunction with the amplification of the trigger pulse. The major disadvantage of this circuit is its poor frequency stability.

The period of the circuit shown in figure 10-4 is determined by the values of R1, R2, and C1 which comprise the time constant of the discharge circuit. The pulse repetition period is determined by the equation

$$T = (R1 + R2)\ C1\ \log_n \frac{E_i}{E_f}$$

where E_i is the initial voltage across R1+ R2 at the beginning of discharge, and E_f is the final voltage across R1 + R2 at the end of discharge. C1 also contributes to the determination of the pulse width.

Synchronized

The synchronized blocking oscillator is used as the timing oscillator in auxiliary equipment whose timing must be synchronized to that of the radar. Normally, the radar produces its own PRF independently (the PRF oscillator is free-running.) Synchronizing pulses can be introduced at the plate of a blocking oscillator without changing its circuit to vary the PRF. The sync pulse amplitude is such that a predetermined pulse makes the circuit operate. The oscillator may be synchronized on alternate pulses, or on other submultiples, as well as on each pulse. By synchronizing the auxiliary set with the radar, indications can be displayed on the main indicator, relieving the operator of the need to monitor two indicators at the same time.

The amplitude of the synchronizing pulse has a great effect on the frequency of this circuit. If the amplitude of the synchronization pulse shown is increased, the first pulse after the circuit begins operation brings the grid above cutoff and the circuit is synchronized on every pulse. A lower amplitude pulse could cause triggering on every second or third pulse.

In each case, it is assumed that the natural period of the circuit is longer than the time between the pulses which cause the circuit to operate. If the period of the blocking oscillator is shorter, it produces long and short cycles because the circuit is triggered on some pulses but conducts on its own accord at times.

AT.156

Figure 10-4.–Free-running blocking oscillator.

Driven

Some electronic circuits require a blocking oscillator which operates only when triggered. Such a circuit might be called a BLOCKED OSCILLATOR (since a permanent d-c blocking voltage prevents the circuit from oscillating of its own accord). In this type circuit only a positive voltage on the grid or a negative voltage on the cathode can cause the tube to conduct. If the voltage is a pulse, the circuit goes through a cycle of operation, cuts itself off, and the d-c voltage maintains it below cutoff. Cutoff is maintained by a voltage divider from the plate-supply voltage.

The trigger pulse must be large enough in amplitude to start a cycle of operation. The normal discharge of the grid capacitor reduces the grid voltage after a cycle of operation, but the discharge does not raise the grid bias to the cutoff level, so the circuit does not again conduct without another trigger pulse. The positive trigger pulse is applied to the grid. The output may be taken from the plate, where a large negative pulse is available, or from a

13419

UNIT II - USE OF DRAWING INSTRUMENTS

Scales Lesson 3

OBJECTIVE: To learn how to interpret and use a scale.

RELATED INFORMATION:

In the making of working drawings, the draftsman must be precise and prepared to draw an object either full size, or, if necessary, smaller or larger. Therefore he should possess full command of the proper usage and reading of scales. There are many scales to choose from with different graduations and styles, but for our purposes we shall study the two most common types, the mechanical engineer's flat scale and the architect's triangular scale.

FIG. 1

The mechanical engineer's scale shown in Fig. 1 is divided and numbered so that fractions of inches represent inches. Each "inch" is divided into halves, quarters, eighths, sixteenths and thirty-seconds. A full and a half-size scale are also included. These scales are also often graduated with the marked divisions numbered right to left, as well as from left to right. Mechanical engineer's scales are used mostly for drawings of machine parts and small structures.

FIG. 2

The architect's scale is shown in Fig. 2. It is divided into proportional feet and inches with divisions indicating $\frac{1}{8}$, $\frac{1}{4}$, $\frac{3}{8}$, $\frac{1}{2}$, $\frac{3}{4}$, $1\frac{1}{2}$, and 3 inches to the foot.

third transformer winding where a pulse similar to the plate pulse can be obtained with either polarity.

SWEEP GENERATORS

Sweep generators are used to develop a waveform of voltage which changes level gradually over a period of time. Common uses of this type waveform include CRT sweep and deflection systems, local oscillator AFC tuning systems, certain classes of variable time delay systems, and FM modulating systems. The voltage variation is basically a sawtooth type waveform, but it may be modified to a trapezoidal waveshape for certain applications. It may be generated continuously, or it may be intermittently triggered or gated.

Theory of operation of the basic sawtooth generator is discussed in Basic Electronics. One major disadvantage of that circuit is its inability to generate a linear sweep of voltage. The output voltage wafeform is normally taken across a sweep capacitor; a capacitor always charges exponentially. If only the first 10 percent of the capacitor's charging curve is used, the waveform is considered to have adequate linearity. Under these conditions, the magnitude of the output waveform is small.

Bootstrap Sweep Generator

The bootstrap sweep generator develops a linear sawtooth of voltage which has relatively large amplitude. The circuit shown in figure 10-5 produces a positive-going voltage rise during the application of a negative-going rectangular pulse.

In this circuit, V1 acts as a switch to control the charge and discharge of timing capacitor C3. The cathode follower, V2, and the bootstrap diode, V3, provide a means for making the charging curve linear instead of exponential.

In the absence of a negative gate, all three tubes are conducting. Most of the B-plus voltage appears across R3 and R4, and capacitor C2 is charged nearly to the B-plus voltage. Timing capacitor C3 is charged only to the low plate potential of V1.

A negative gate input to the grid cuts off V1. The timing capacitor, C3, starts charging

Figure 10-5.–Bootstrap sweep generator.

through R3 and R4. The rising voltage on C3 is applied to the grid of cathode follower V2. The voltage on C3 and the grid of V2 begins to rise toward the voltage of C2. The cathode current of V2 increases, increasing the voltage drop across R5. This increase of voltage is added to the voltage of C2; the cathode of V3 becomes more positive. Thus the voltage drop remains relatively constant as C3 charges.

With a constant voltage across resistors R3 and R4, the current is constant, and the voltage on C3 rises linearly. The output is taken from the cathode of V2. The bootstrap diode V3 ceases to conduct when the potential of its cathode rises above that of its plate, and effectively disconnects the charging circuit from the B-plus supply. Thus, the voltage of the linear waveform is not limited to the B-plus voltage but continues to rise linearly until the negative gating pulse is removed from the grid of V1. When V1 again begins conducting, C3 discharges to its static low voltage level, and the extra voltage across R5 disappears. Since the cathode of V3 is then slightly less positive than its plate, the tube conducts. The generator remains in this static state until another gating pulse arrives at V1.

13420

Trapezoidal Waveshape Generator

The sawtooth sweep generator is suitable for an electrostatistically deflected CRT. However, most radar sets employ magnetic deflection; sweep voltages are applied to coils. In long range sweeps, the sawtooth voltage is adequate for the desired linearity, but on short ranges, a special sweep voltage with a trapezoidal waveform must be applied to overcome the inductance of the sweep coils. (This topic is discussed later in this chapter.)

A simplified trapezoidal waveshape generator circuit is shown in figure 10-6. The circuit shown is a modification of the sawtooth generator circuit. Note that a resistor, R2, is connected in series with the timing capacitor, C, to ground. The triode serves only as a high speed switch to control the charging and discharging of an RC circuit.

When the tube is cut off (switch opens) by the negative input pulse, the plate voltage rises toward the applied B-plus voltage. The voltage rise is at the rate at which the timing capacitor, C, charges. In an RC circuit, at the first instant of a switching action, the entire voltage present in the circuit is impressed across the resistance; the capacitor charge cannot change instantaneously. However, some of the resistance of the RC circuit (that voltage impressed across R2) is between the plate and ground. This causes a voltage division, and the output voltage (as indicated in fig. 10-6) jumps immediately toward the applied voltage.

The applicable waveforms are shown in figure 10-6 (B). The total of the capacitor voltage plus the sum of the individual resistor voltages always equals the full voltage effectively present in the circuit. The resistive voltage is divided proportionately according to the individual resistances. The curve for R2 voltage is thus a miniature replica of the total resistive voltage.

The output voltage waveform of this circuit is the sum of the R2 voltage and the capacitor voltage. This is the waveform shown in the last graph of figure 10-6 (B), and represents the trapezoidal waveform of voltage required by the electromagnetic deflection sweep coil circuits.

Miller Sweep Generator

In the Miller linear sweep generator (fig. 10-7) the suppressor grid is normally biased negative to prevent plate current flow, while the

AT.158

Figure 10-6.—Trapezoidal sweep generator.

13421

screen conducts heavily. The control grid is returned to B-plus through a resistor so that it is effectively at zero potential, and the cathode is grounded. Observe that the screen is not coupled, that a separate bias source is used for the suppressor, and that an external sweep gate is necessary.

When a positive gate is applied to the suppressor, plate current flows and produces a voltage drop across the plate load resistor. This negative swinging plate voltage is fed back through a small capacitor to the grid, and quickly drives the grid negative. It maintains the plate current at a small value and greatly reduces the screen current.

Reduction of the heavy screen current produces a large positive swing on the screen. The tube remains in this condition, producing a positive screen gate. Meanwhile the plate current (under control of the feedback voltage applied to the grid) flows until no further feedback is produced. During this time the plate current increase is linear, and the plate voltage continues to drop.

AT.159

Figure 10-7.–Miller linear sweep generator.

The normal discharge of C through Rg would cause the current through the tube to increase in an exponential manner, causing the plate voltage to drop exponentially. However, any exponential change is fed back to the grid 180° out of phase with the normal discharge of C, causing a linear increase in plate current.

At a point about 2 volts above ground, no further plate swing is possible. The screen again conducts heavily, returning almost to the initial operating point. When the suppressor gate ends, the plate current is cut off, the screen returns to its initial operating point, and the cycle is ready to be resumed under control of the next gate.

Changing the applied plate voltage determines the point, and the time, at which the plate voltage reaches a minimum (with respect to the leading edge of the input waveform) and the screen resumes control. Changing the values of feedback capacitor C and grid resistor R will also determine the time of operation (by controlling the speed of the grid-plate feedback action).

TIMING AND PULSE GENERATORS

Many avionic systems require accurately timed sequences of operation. Radar systems demand various degrees of accuracy in PRF and pulse width. TACAN and IFF systems depend on pulse-pairs which have specific time intervals between the individual pulses of a pair. Computers and data systems rely on synchronization between clock and data pulses. CRT's are normally blanked during retrace, and the sweep may be delayed for various time increments from the initiation of the overall operating cycle.

Synchronization and time-sequenced operation are usually accomplished through the use of pulses. The time duration of these pulses may be relatively short (trigger) or relatively long (gate). In synchronous operation, the functions may occur simultaneously or one operation may be delayed for some time period from the occurrence of another.

Many of the circuits used in timing and pulse generations are also used for other functions. The present discussion is devoted to brief indications of the functions performed by these

13422

circuits, followed by a discussion of the phantastron delay circuit.

Pulse Generation

The use of a sinusoidal waveform in synchronizing a multivibrator is discussed in Basic Electronics, NavPers 10087-B. The sine wave may also be used as the basic source of timing pulses. One such system requires the use of limiters (or overdriven amplifiers), differentiators, sweep voltage counting circuits, and triggered pulse generators.

In the system outlined above, the clippers are used to convert the sine wave to a square wave. The differentiator circuit converts this square wave into voltage spikes. The spikes are then superimposed onto a sweeping voltage waveform to govern the selection of the specific spike to be used in the generation of the delayed pulse.

Relatively short time pulses used for triggers are frequently generated by blocking oscillators. They may, however, be produced by differentiating the output of a multivibrator.

The longer time pulses required for gating are normally produced by multivibrators.

Time Delay

Time delay circuits are utilized when two or more functions must be performed with a specific time relation, but not simultaneously. Such a time relationship may be either fixed or variable. Variable delays may be in multiples of a designated interval, or they may be smoothly variable with no relationship to any specific interval.

Incremental delay circuits normally incorporate a basic generating circuit and a counting circuit. In the synchronized blocking oscillator discussed earlier, operation may be synchronized by an associated sine wave. By proper operation of the blocking oscillator circuit, synchronization may occur on the first, second, third, etc., cycle (of the synchronizing waveform) following the last triggering action. In this system, the blocking oscillator acts as its own counter.

Another type of incremental delay circuit uses a separate counter circuit. In radar range mark systems, an accurate and stable basic generator is used to develop signals corresponding to 1 radar range mile. A counter circuit is then used to produce an output corresponding to 2, 5, 10, etc., miles.

Another circuit which is used to provide a time delay function in electronic equipments is the monostable multivibrator discussed previously. This circuit may be activated simultaneously with the first of the time sequenced operations. Its output is then used to activate another circuit at the instant the multivibrator regains its stable state. The operation of the second circuit is thus delayed with respect to the first. The system time delay is equal to the time duration of the unstable state of the multivibrator.

Phantastron Circuit

The phantastron circuit is a relaxation oscillator similar in operation to the multivibrator. The multivibrator derives its timing waveform from an RC circuit; the phantastron uses a basic Miller type sweep generator. The output waveform of the phantastron is a linear function of the input (control) voltage.

The phantastron is usually triggered on by the leading edge of a gating or trigger pulse, and is shut off by an internally generated waveform. It can also be shut off by the trailing edge of the gate or by a trigger.

Because of its extreme linearity and accuracy, the phantastron output is used as a delayed timing pulse, usually in radar or display equipment. It is also used to produce time-delayed trigger pulses for synchronizing purposes and movable marker signals for display.

SCREEN-COUPLED CIRCUIT.—A typical monostable screen-coupled pentode circuit is shown in figure 10-8. This circuit is started by a positive trigger applied to the suppressor grid, and at the end of operation it returns to the initial starting condition, ready to repeat its cycle of operation when the next trigger arrives.

Three steps are involved in the circuit action—turnon, linear sweep development, and turnoff. The waveforms developed in the tube elements are shown in figure 10-8 (B). Before initiation of action, the circuit is resting with the plate current cut off, due to a negative voltage applied to the suppressor through R3. Resistors R1, R2, and R3 form a combined suppressor and screen grid voltage divider con-

13423

nected between B-plus and C-minus. The values are such that the screen is positive and the suppressor is sufficiently negative to cut off plate current. Since they are directly connected, both elements are d-c coupled; also, through capacitor C1 they are a-c coupled. Therefore, both d-c and a-c voltages appearing on one element also affect the other element.

AT.160

Figure 10-8.–Basic screen-coupled phantastron.

Since the cathode is grounded and the grid is connected through R5 to B-plus, the grid remains near zero bias. Thus, although the plate current is cut off, the screen current is heavy. When a positive trigger is applied to the plate of disconnecting diode V2 through coupling capacitor Cc, the diode conducts. The positive trigger thus appears across R3 and is applied to the suppressor of V1. The trigger is large enough to overcome the fixed negative bias and drive the suppressor positive. Therefore, plate current flows through R4. (Since R4 is a relatively large value resistor, the plate current quickly goes from zero to a low value; simultaneously, the negative swing produced across R4 is applied through C to the grid, driving it from zero to a negative value. This value is only a few volts, but is sufficiently negative to reduce the total cathode current.)

The grid is now in full control, and the reduction of screen current produces a large positive increase in screen voltage. The positive-going screen voltage is fed back through C1 to the suppressor, so that the action is regenerative. As a result, the tube is quickly triggered from the static condition to the operating condition, which produces a screen waveform with a sharp leading edge. The linear sweep development or timing cycle now begins, with the plate current of V1 increasing steadily.

Since the grid is returned to B-plus, the grid voltage attempts to reach the zero bias level. It can change only slowly, however, because the plate side of feedback capacitor C is steadily decreasing. Any positive grid swing is immediately counteracted by a negative plate swing fed back to the grid. Therefore, capacitor C starts to discharge and electrons flow from the plate of V1, discharging C through R5. (Thus C discharges at a rate determined by the time constant of C and R5.) In some circuits, R5 is made variable to permit changing the rate of operation.

In discharging, the grid side of capacitor C gradually becomes more positive, causing an increased current flow through R4 and producing a constant decrease in plate voltage. The positive increment on the grid is always slightly greater than the negative plate swing it produces; therefore, the grid potential gradually rises, and the plate potential gradually drops. When the plate reaches the point where a voltage change on

the grid will produce no further plate-voltage change, the turnoff point is reached.

Up to this time a positive gate has been produced in the screen circuit and coupled to the suppressor. A negative gate has been developed on the grid which is slightly smaller in amplitude from the leading edge to the trailing edge. The amount is dependent upon the gain of the tube.

The tube plate voltage is now only a volt or so above zero and the plate current can no longer increase. The grid voltage, however, is still rising toward zero, causing an increase in total current flow. Therefore, the screen current increases. The moment the screen current increases, the screen voltage drops and feeds back a negative swing through C1 to the suppressor. The suppressor grid then resumes its original negative condition, stops any flow of plate current, and assumes control again.

Since this action is regenerative, a sharp trailing edge is produced. Simultaneous with plate current cutoff, the plate voltage swings positive and feeds back to the grid a positive voltage, which helps the grid to return to normal zero bias condition. Since the charge on C cannot change instantly, the plate swing tapers off exponentially and the tube is not ready for another trigger cycle until it has completely recovered.

Diode V3, called a "plate-catching" diode (because of the way it "catches," or arrests, the positive excursion of the plate voltage), operates to catch the plate at a specific voltage. Thus, with a fixed bottoming point, the length of the output pulse (and its time duration) depend on the plate voltage fixed by V3. The cathode of V3 is biased positive by the voltage divider consisting of R6, R7, and R8, as controlled by potentiometer R7. When the plate voltage of V1 is greater than the positive voltage applied to the cathode of V3, the diode conducts and quickly bring the plate voltage of V1 down to the level of the cathode voltage.

The linear sweep action always starts at the voltage set by R7, and the duration of the phantastron gate (or the length of the sweep) is thereby determined. Because the amplitude of the plate sweep depends on the level at which it starts, R7 directly controls the amplitude. The amplitude of the screen gate is determined by the voltage applied and the screen current, and is only slightly affected by R7.

Operation occurs at a rate fixed by the discharge of C through R5. In some circuits R5 is made variable to set the maximum time delay, and R7 is provided as an external control to permit selection of the exact time duration required. Feedback capacitor C provides regenerative feedback from plate to grid, to allow quick response to any changes in the plate circuit.

CATHODE-COUPLED CIRCUIT.–A typical cathode-coupled pentode is shown in figure 10-9. This circuit is also started by a positive trigger applied to the suppressor grid and turns itself off automatically. The output can be taken from either the screen or cathode, or both. The screen output is a positive gate, and the cathode output is a negative gate.

In this circuit, tube V1 is the basic phantastron, with diode V3 operating to control the plate voltage level and determine the duration of the output gate. To minimize overshoot (positive on the control grid and cathode, negative on the screen grid), diode V2 is connected between R1 and R2 on a voltage divider network consisting of R1, R2, and R3.

The voltage on the cathode of V2 is normally 1 or 2 volts less than the cathode voltage of V1.

AT.161

Figure 10-9.–Basic cathode-coupled phantastron.

13425

No negative supply is needed to bias the suppressor; cathode bias is used, and the suppressor is held at a lower positive potential than the cathode. Thus, the suppressor is effectively biased negative with respect to the cathode, cutting off plate current. The screen is drawing current, which produces a positive voltage on the cathode. When a positive input trigger appears across R3, it is applied to the suppressor. This trigger is prevented from affecting the control grid by automatically reverse-biasing diode V2.

The grid is normally biased near zero, being held by diode V2 at a potential determined by the voltage divider (R1, R2, and R3) connected between B-plus and ground, and the cathode is positive with respect to the grid by approximately 1 or 2 volts.

When the trigger is applied, it overcomes the bias between the suppressor and cathode, and plate current flows. The decrease in plate voltage, due to the flow of plate current, is fed back to the grid through capacitor C. This causes the tube current to decrease and the cathode voltage to drop. The drop in cathode voltage further decreases the bias between the suppressor and cathode, and plate current increases further. Since the total tube current is decreasing and the plate current is increasing, the screen current must decrease. This action is regenerative, and plate current will jump from zero to a value determined by the tube characteristics.

Note that the bias between the cathode and suppressor is decreasing, causing the plate current to increase. The bias between the cathode and grid is increasing. This degenerative action decreases the total tube current. Therefore, there must be a point where these two effects are equal and the current will stabilize for an instant. At this instant there is no further change in plate voltage, and the grid voltage increases in the positive direction (at a rate determined by C and R5) since it is returned to E_{bb} through resistor R5. This causes the plate current to increase.

As the plate current increases, the plate voltage decreases, and this negative change is coupled through C to the grid. This signal is degenerative, and prevents the plate current from increasing rapidly. This action continues, providing a linear sweep until the plate voltage drops to a level at which it can no longer cause an increase in plate current. At this time, degenerative feedback to the grid stops, and the grid goes in a positive direction more quickly. This causes an increase in the total tube current, and thus an increase in cathode voltage, an increase in cathode-to-suppressor bias, and a decrease in plate current.

With the total tube current increasing and the plate current decreasing, the screen current must be increasing. The action taking place is regenerative, as the plate goes positive, the grid goes positive; the plate current goes rapidly to cutoff, leaving the tube in its pretriggered condition. The positive swing in the grid is limited by the catching diode, V2. Before the circuit is ready for the next cycle of operation, capacitor C must recharge through R3, R2, V2, and R4.

RESHAPING CIRCUITS

Many different waveshapes are required in the operation of modern electronics equipment. These various waveforms are frequently generated in one form and must then be reshaped into another form for use in specific circuits. Various pulse type waveforms are sometimes deteriorated or distorted by circuit components; they must then be reshaped for use.

The basic operation of many reshaping circuits is discussed in Basic Electronics; the present discussion comprises a brief summary of the main functional applications.

LIMITERS AND CLIPPERS

The basic function of a limiter (also called a clipper) circuit is to control the extreme excursions of a waveform. The circuit accomplishes this function by removing (clipping) any portion of a waveform in excess of specified limits. Thus it limits the maximum excursion of its output waveform by clipping the extremities of the signal.

The circuit, with appropriate changes, may be used to limit the positive or the negative portion, or both. It may also incorporate amplification of the waveform, although this feature is not essential to its operation as a clipper.

Functional applications of clipping circuits include the following general classes:

1. Changing the basic shape of the waveform by eliminating the top (and/or bottom) by clipping.

13426

2. Improving the basic shape of the waveform by eliminating the overshoots and/or undershoots on leading and trailing edges.

3. Improving the usefulness of a waveform by clipping each cycle to the same amplitude.

4. Improving the usefulness of a waveform by making each cycle have the same time duration.

5. Eliminating possible interference in the overall system by eliminating pulses of the wrong polarity.

CLAMPING CIRCUITS

Clampers, although not actually reshaping circuits, are frequently associated with limiters in functional classification. One of the disadvantages of limiters used alone is that they tend to operate around an average voltage which is established by the signal voltages. Clampers are used to overcome this fault by establishing either a positive or negative reference to which the signal voltage variations are referenced before clipping.

DIFFERENTIATORS AND PEAKERS

This class of reshaping circuits makes use of the exponential charge and discharge characteristics of RC and L/R circuits. "Differentiator" usually refers to RC circuits having a relatively short time constant with respect to the period of the input waveform. "Peakers" are usually L/R differentiators.

These circuits are normally used in pulse systems; their main application is to produce a peaked waveform or spike output. Used with square or rectangular inputs, they produce output spikes of alternate direction which are coincident with the leading and trailing edges of the input. Time duration of each pulse peak depends on the charge/discharge time constant.

INTEGRATORS

The differentiating circuit may also be used as an integrating circuit by merely changing the output tap. Differentiating circuit outputs are normally taken across the resistive component; integrators use the reactive component waveform.

RESONATORS

Some electronic equipments require oscillatory signal generation only during specified intervals. One example of this requirement is the magnetron oscillator used in pulsed radar systems. In this example, a pulse of voltage is applied to the magnetron for a short period, and then is removed for a considerably longer period. The magnetron oscillates only during that period when the pulse is applied. Effectively, a rectangular waveform of voltage has been "reshaped" into sinusoidal waveform oscillations—but only intermittently.

The same general principle is used in some range mark circuits. When the transmitter magnetron is fired, a gate circuit is also generated. This gate has a time duration approximately equal to the time required for maximum range operation. A relatively high frequency oscillator is gated by this waveform so that it produces variations to be used in the generation of range marks for timing purposes.

Another type of resonator is the ringing oscillator, where a signal is injected into a tuned circuit, which then oscillates at its resonant frequency. This type circuit is common in frequency multiplier applications, and in resonant cavities which are discussed in chapter 11 of this manual.

COUNTING CIRCUITS

A level counting circuit is one which receives uniform pulses, representing units to be counted, and produces a voltage proportional to the frequency. Either positive or negative pulses may be counted, requiring only minor changes (in the connections of the diode counting element).

With certain other modifications to the circuit, the counter may also be used, in conjunction with generating circuits, to produce a trigger pulse which is a submultiple of the PRF of the applied pulses.

All pulses applied to the counting circuit must have the same amplitude and time duration if an accurate frequency division or counting is to be made. Therefore, this circuit is usually used in conjunction with pulse shaping and limiting circuits. These circuits are used to insure

13427

standardized input pulses, with uniform amplitude and width. Pulse frequency then represents the only variable; this permits accurate measurement of the frequency variations, or division of the pulse repetition frequency.

Operation of the basic circuits is discussed in Basic Electronics. Several examples of their functional application have been presented in earlier discussion in this chapter.

OTHER CIRCUITS

Since the duration of the output waveform of the monostable multivibrator can be made almost constant, this circuit can be used as a pulse restorer. Given an input waveform of varying width, the circuit can produce output pulses having a constant duration. Many digital computer equipments make use of this circuit to restore the shape of deteriorated clock and data pulses after circulation and prior to storing.

Video mixers are frequently used to combine several individual waveforms into a single, more complex waveform. Although not a reshaping function, it should be mentioned in this section.

DEMODULATING CIRCUITS

Demodulating circuits accept composite signal inputs and separate them into their component parts. Two basic classes of demodulating circuits are considered in this discussion. The first class extracts the intelligence component from the composite input, the other class eliminates an undesirable component of the signal. The classes are distinguished by basic intent, rather than by the overall results obtained.

For example, in an amplitude modulated radio wave, the intelligence is carried in the audio component of a composite signal. In the detector circuit, this audio component is extracted from the wave. The same composite wave also contains undesired components of noise; these components are eliminated from the composite signal by filters, and by squelch and muting circuits.

Chapter 10 of Basic Electronics contains a discussion of some basic demodulating circuits. The basic circuits discussed include several types of AM detectors and several types of FM detectors. In this discussion, AM detectors are discussed under the heading "Detectors," while FM detectors are discussed under the heading "Discriminators." Noise detectors and eliminators are discussed under the heading "Squelch and Muting Circuits."

DETECTORS

All detectors incorporate nonlinear devices and signal-selective filtering. The diode is a simple device possessing nonlinear characteristics, and is the active element most commonly used in this application. The diode may be a semiconductor or a vacuum tube.

In the common diode AM audio detector circuit, the composite signal is first rectified, then the RF component is filtered out. This leaves only the audio signal component, which is then amplified and used to reproduce the transmitted intelligence. Other types of detectors perform effectively the same functions.

In the detection of AM signals, rectification is essential. The signal variations (envelope) are effectively sinusoidal in amplitude, varying about an average (reference) value. Filtering out the RF component without previous rectification would leave only the reference value, which does not vary. By the preliminary rectification process, however, one-half of the RF variations is eliminated, leaving the other half (which varies sinusoidally at an audio rate). The average (reference) value of the remaining portion of the signal does vary, so that subsequent filtering out of the RF component leaves the audio signal variations (which contain the impressed intelligence).

DISCRIMINATORS

AM detectors, as discussed previously, respond primarily to variations in the amplitude of a composite signal. FM detectors, however, respond primarily to frequency variations, although they are somewhat sensitive to amplitude variations also. Variations in the amplitude of the applied signals tend to produce distortion in the output signal, therefore most FM detectors are preceded by one or more stages of amplification and a limiting circuit.

Theory of the basic types of discriminators is presented in Basic Electronics. Three actual discriminator types in common usage are dis-

13428

AT.162

Figure 10-10.–Discriminators.

To become an accurate draftsman, it is imperative to learn to use the scale correctly. When making measurements, be sure to lay the scale close to the line and look directly down on the point where the measurement is to be made (Fig. 3) and mark the point on the paper with a well-sharpened pencil point.

FIG. 3

ASSIGNMENT:

Give the correct measurement for each of the illustrations shown below.

1

2

3

4

cussed briefly in the following paragraphs. Emphasis is placed on the differences and similarities between the circuits, rather than on the operation of the individual types. Figure 10-10 (A) illustrates some of the basic terminology involved in the discussion; sections (B), (C), and (D) of the same figure show simplified circuit diagrams of the discriminators discussed.

The zero reference (fig. 10-10 (A)) may be at some d-c level other than at ground potential. The "zero" level to which polarities are referred in the discussion is the d-c voltage at the output terminals with no signal at the input terminals. The crossover frequency is the frequency lying between the two output peaks for which the output voltage is zero.

If the IF input signal consists of continuous waves, the output voltage will be d-c. If the IF input signal is in the form of a series of short pulses, the output voltage will consist of a series of pulses whose amplitude and polarity vary as indicated in figure 10-10 (A).

The TRAVIS type discriminator circuit depends upon the action of two resonant circuits. One is tuned above the desired crossover frequency and the other is tuned below. Detectors across the two circuits are connected back-to-back. The individual resonant elements are double tuned.

When close coupling is used, each side of the discriminstor characteristic may be double humped. (This is not possible in either of the other circuits.) If the peak-to-peak separation is too great for the circuit Q's in any of the circuits, the characteristic will have a "chair" shaped waveform.

Three factors may be adjustable. Crossover frequency may be shifted by tuning the two resonant elements in the same direction. Peak-to-peak separation may be adjusted by tuning the two circuits in opposite directions. A slight adjustment of the primary circuit adjusts the symmetry of the overall circuit response.

In the FOSTER-SEELEY discriminator (fig. 10-10 (C)) the mutual inductance determines the peak-to-peak separation while the crossover frequency is the resonant frequency of the secondary.

The Weiss discriminator (fig. 10-10 (D)) was developed in an attempt to reduce the detrimental effect of stray capacitances by making them serve a useful function. This is essentially the capacitance-coupled analog of the Foster-Seeley. These two discriminators have substantially identical electrical performance (gain-bandwith product).

The Weiss requires accurate control over the small difference between values of the coupling capacitors (required for a narrow band characteristic). The Foster-Seeley suffers at large bandwidths because of the large variation in mutual inductance with small displacements of the coils.

SQUELCH AND MUTING CIRCUITS

As stated previously, detector and discriminator circuits are used to extract usable components from a composite signal. Squelch and muting circuits, on the other hand, are used to extract and eliminate undesirable components from the signal. Detectors and discriminators usually accept RF or IF inputs and supply audiofrequency outputs. Squelch and muting circuits usually have noise or distorted audiofrequency inputs from which the noise and distortion are to be eliminated.

The distinction between squelch and muting circuits is quite vague. In actual practice, the same basic circuit is referred to as both squelch and muting.

Squelch circuits are usually found in ICS of in sensitive communications receivers which incorporate automatic gain control circuits. The squelch circuit is used to perform one or both of the following functions:

1. To reduce the objectionable increase in the noise output level as the receiver is tuned from one station to another.

2. To silence the receiver audio output or the ICS until a signal of usable magnitude is received.

Figure 10-11 illustrates a simplified version of a common squelch circuit.

With this type of circuit it is desirable for the receiver to come into operation with the weakest possible signal voltage. To achieve high sensitivity without excessive background noise from various sources, it is desirable to have a variable "threshold" control. This control, which is located in the cathode circuit (R8 and C3) varies the amount of bias on the squelch tube and therefore controls the sensitivity of the circuit. The squelch tube is used as a d-c amplifier to

AT.163

Figure 10-11.–Typical squelch circuit, simplified.

control the amount of bias on the first audio stage.

With no input signal to the receiver, the AGC delay voltage (which is positive) appears on the grid of the squelch tube, causing the tube to draw maximum current. The current flowing through the high value plate resistor produces a voltage drop at the grid of the first audio, cutting off the stage.

For signal conditions, the grid of the squelch tube becomes negative, due to AGC action, so that this stage is cutoff and the first audio amplifier operates at normal gain.

The cathode circuit of the squelch is completed through a switch, which is normally closed. By opening the switch the squelch is made inoperative. The bias on the cathode is varied from maximum to minimum sensitivity by the threshold control R8.

COUPLING CIRCUITS

The term "coupling circuits," properly used, includes any circuit or component grouping which is used to convey the output of one functional circuit or stage to the input of another. Thus, the methods used for connecting the individual stages of amplification (discussed in Basic Electronics) are included in the general term. Also included are the various feedback methods used to produce regenerative or degenerative action in various types of circuits.

In this chapter, the discussion of coupling circuits includes tuned circuits (filters and wavetraps), transmission lines of various types and applications, delay lines (natural and artificial), and impedance matching and attenuation devices.

FILTERS AND WAVETRAPS

Chapters 3 and 4 of Basic Electronics contain a discussion of the basic theory of LCR filter circuits. The following discussion points out some important characteristics of filters and describes some other types of filters.

In electronic applications, the term "filter" refers to a frequency-selective device which operates on the basis of reactance. The usual measure of the effectiveness of a reactor device is the "quality factor (Q)." The value of Q is the ratio of the reactance to the series resistance of a coil or capacitor. The higher the value of Q, the better the filter that can be designed.

As discussed in chapter 9 of this manual, values of Q in lumped components at radio frequencies are quite limited. At progressively higher frequencies, increased use is made of the distributed properties of L and C. This permits the attainment of higher values of Q than are attainable in lumped components.

In electronic design, gain is usually cheap, but selectivity is expensive. Since filters must be frequency-selective, they are usually designed to provide the special characteristics required for their specific applications.

Characteristics of Filters

The frequency response of a circuit is a plot of the output signal strength or magnitude over a range of frequency variations, using an input of constant amplitude. Frequency response is the basis for classification of filters as low pass, high pass, band pass, and band reject. Wavetraps are usually used as band reject filters placed in the input stages of a receiver to eliminate a signal with a frequency which would cause excessive interference with reception.

Filters provide differences in output magnitudes by introducing varying amounts of attenuation at different frequencies. In addition, being reactive devices, filters introduce varying amounts of phase shift to the signal.

This phase shifting characteristic is especially important in equipments using pulse signal systems. Rapid changes in signal voltage must not generate large overshoots or undershoots. (Such conditions could damp desired oscillation, or they could cause undesirable oscillation.)

The "group delay" characteristic refers to the relative phase shift (delay) of the various frequency components of a waveform as the signal travels through the filter. A flat group delay response is usually desired because such a curve indicated that all passed frequencies are delayed by an equal amount. This reproduces the desired signal with minimum distortion. If unequal amounts of delay are desired, the filter elements must be adjusted accordingly.

Filter Types

Several types of filters other than the lumped LCR devices are used in electronic circuits and equipments. Most of these types make use of some form of resonance or near resonance as the basic operating principle.

The piezoelectric crystal resonator has a Q of several thousand. It is also relatively stable with time and environmental conditions. With such resonators, filters with high selectivity and very narrow bandwidths have been developed. The crystal, however, tends to oscillate in modes other than the fundamental frequency. The spurious modes are undesirable and unpredictable, thus limiting the usefulness of this type filter. When used, it is usually within the range of several kHz to about 20 MHz.

In single sideband applications, the mechanical filter (described in chapter 16 of this manual) is used extensively. An interesting characteristic of this type filter is its frequency response curve–sharp cutoff on one end, sloping response on the other.

Many types of filters make use of resonance in distributed properties. These include various types of transmission lines, coaxial resonators, waveguide sections, resonant cavities, etc. The July 1964 issue of the DIGEST contains an article which discusses filters in electronics.

PRESELECTOR FILTERS.–These filters are required at the input (front end) of all sensitive receivers to separate the desired signal or signals from the unwanted signals. Because the desired signal is always low in amplitude while the undesirable signals, including noise, may be appreciably greater, the preselector must have a low insertion loss to the desired signal and high attenuation to undesirable signals.

SSB FILTERS.–In contrast with the very symmetrical preselector filters, the single sideband filters for a modern communication scheme require nonsymmetrical attenuation on opposite sides of the passband; indeed, the filters in such a scheme become the heart of the system. Sometimes, instead of filters, phase difference networks are used to eliminate the unwanted sideband. In either case the purpose of the network is to suppress the second sideband to such a degree that it does not contribute appreciably to the amplitude distortion and instability of the received signal.

COMB FILTERS.–The optimum filters can extract a predetermined signal from a medium where noise is prevalent or jamming is introduced. In general, the optimum filter is a device whose input consists of a signal representing the mixture of information-bearing signal and noise. At the output of this same filter, only a signal closely approximating the useful signal will be present. This is a most important application of information theory. For a signal represented by a periodic series of pulses such an "optimal" filter will be a "comb" filter which consists of a chain of narrow band filters passing spectral lines over the frequency spectrum of the signal. The comb filters pass discrete frequency components and discriminate against noise.

MULTIPLEXING FILTERS.–These filters provide multiple use of a broad frequency spectrum beam between terminal stages of a radio relaying system. It is possible to create up to one thousand telephone channels in one microwave link. In the case of a wire carrier communication network, the frequency range extends from the audio band up to 200 kHz (the same for power line communication). The use of coaxial lines widens the range of frequencies, and more communication channels can be created. The one requirement of such a filter is to obtain the sharpest possible attenuation outside of the pass band to suppress crosstalk between channels.

ANTIJAMMING FILTERS.–Artificially created noise for jamming can completely destroy the target signal if no antijamming features are

point vary sinusoidally, the positions at which the maxima and minima occur do not move.

The terms maximum and minimum points, as used above, do not imply that the value of voltage or current at a point remains constant. The instantaneous values vary sinusoidally, as stated. At a maximum point, however, the value at any instant is greater than that at any non-maximum point at the same instant. As in any sinusoidal variation, the polarity of the signal reverses each half-cycle.

The extremes of unmatched impedances used for terminating a line are the open circuit and the short circuit. A line with an open circuit termination displays a voltage maximum at the load end, and at each half wavelength from the end. The current at the termination is minimum, with a maximum current point occurring at the voltage minimum points. A line with the short circuit termination displays the opposite characteristics.

Lines with terminal impedance other than those mentioned above display standing waves, with intermediate voltage and current values at the end, and with the minimum and maximum points shifted to positions toward or away from the termination.

In a line terminated with an impedance greater than the characteristic impedance, the voltage maximum will appear less than a quarter-wavelength from the end. Terminated with an impedance less than Z_0, the voltage maximum will be more than a quarter wavelength from the termination. Relative locations of the voltage and current maxima and minima, with respect to each other, remains unchanged; position with respect to the termination, however, does vary with terminal impedance. The magnitude of standing waves also varies with the degree of mismatch between the characteristic and terminating impedances.

The standing waves on a transmission line are used as an indication of the efficiency of the line in energy transfer. The voltage standing wave ratio (VSWR) is the ratio of the voltage magnitudes at the maximum and minimum points. A line which is terminated in its characteristic impedance has no standing waves, as previously stated. The maximum and minimum points do not exist–the voltage is at an equal level throughout the length of the line. Therefore, the ratio of voltage is unity, or the VSWR is 1:1. This represents the maximum transfer of energy, and is called an impedance match. For maximum transfer of energy throughout the system, both the source and the load should be matched to the line. Any impedance mismatch causes standing waves, with a resultant energy loss in the line. Effectively, this constitutes an attenuation of the signal.

Although the previous discussion is based on the two-wire line, the same basic theory is equally applicable to other types. Transmission lines in common avionic usage include the coaxial cable, unshielded twin lead, shielded twin lead, dual coaxial cables, waveguides, high attenuation cables, delay lines, and low noise cables.

ATTENUATORS

Throughout the microwave region, the VSWR of a flexible transmission line may vary over a wide range. The magnitude and the frequency of occurrence of such variations increase with an increase in cable length. The changes in VSWR are due to additive or subtractive reflections. The reflections, in turn, are caused by variations of the impedance at various points along the line. Variations in the diameter or spacing of the conductors, dielectric composition or thickness, or conductivity of the individual conductors cause variations in the L, C, and R components of the sections along the line. At microwave frequencies, small variations result in relatively large reactive components of impedance, with the result that sections of the line may have Z_0 values somewhat different from that of the line. Each variation of Z_0 results in an impedance mismatch and standing waves.

Variations in the Z_0 result in variations of the VSWR. In general, the overall impedance of the line is increased, with resultant increase in signal energy losses. This constitutes increased attenuation, and is usually undesirable. Since the variations tend to increase with length of the line, the lines are usually made as short as possible at microwave frequencies.

For some applications, however, increased attenuation is desirable. Two fundamental methods are used to introduce increased attenuation: the integral and the terminal attenuators.

13434

Integral Attenuators

Integral attenuators are used to decrease the magnitude of a signal in transit through the circuit path. The attenuator may be in the form of a high impedance cable or some other form of attenuating coupler.

High attenuation, or lossy cables, are used to provide isolations of 5 to 20 db between functional portions of a system. They reduce interaction between units which must be separately used in the same system, but whose simultaneous operation could cause undesirable interference with other circuits. This type cable is also used as dummy loads, and is capable of dissipating peak or average power values in excess of those which can be handled by most other fixed attenuators.

The easiest methods of increasing attenuation would be by changing dielectric composition or thickness, or by changing the size, spacing, or composition of the conductors. Increasing the dielectric loss is undesirable because of the variations of Z_0 with frequency changes. The most common method uses a resistive wire as the conductor. This provides increased impedance and attenuation, relatively free of changes caused by frequency variations.

In the common coaxial transmission line system, the limiting factor with respect to VSWR and operating voltage is usually the coaxial connector. The attenuation introduced by the connector is usually fairly small, but it must be considered. Total attenuation increases rapidly with an increase in the number of such devices, therefore the number of connections in a coaxial line is usually kept to a minimum.

In systems where attenuation is desired special attenuating connectors are used. These attenuators usually use a resistive wire center conductor within a circular or rectangular metal box. A conventional coaxial receptacle is normally connected at each end, and the amount of attenuation is stamped on the box. Some devices are available with tapped connections to provide a choice of attenuation. The attenuation value is stamped at each terminal.

Terminal Attenuators

Terminal attenuators are connected to the output end of the circuit. Usually called "dummy loads," their purpose is to dissipate the power developed in the equipment. Normal usage is in the tuning and testing of equipments. The dummy antenna, used in tuning transmitters, permits the loading of transmitter circuits for accurate frequency control but prevents radiation of the energy. Radiation during tuning operations creates signals detrimental to good reception at that frequency.

Use of a terminal attenuator also permits the testing of a section of a system without requiring operation of the section fed by the portion under test.

For proper operation, the terminal attenuator should present the same impedance as the unit it replaces in the system.

DELAY LINES

Artificial delay lines of the electromagnetic type are used to generate rectangular pulses of fixed duration (in radar receiver and transmitter applications); to produce a rectangular waveform from a step function of voltage (as used in starting and delay triggers for test equipment and video display units); to terminate a pulse produced by a regenerative device such as a blocking oscillator or multivibrator (as used in radar, timing circuits, and computers); and to duplicate an existing pulse at a later time (a simple case of time delay). These lines are commonly used for many types of waveshaping and pulse-forming applications.

Delay Cables

Delay cables originated as high impedance cables for better matching of high impedance circuits. High impedance is achieved by increasing the series inductance of the center conductor, which results in phase and attenuation characteristics approaching those of a low pass filter. The parameters are comparatively constant with frequency until cutoff is reached, beyond which the attenuation rises and the delay falls off rapidly.

Delays of less than a hundredth of a microsecond to 10 microseconds can be achieved with cutoff frequencies from 5 MHz to approximately 100 MHz.

These cables are used for pulse-forming networks, phase equalization and timing circuits

f3435

in computers, data transmission, color television, and similar applications. (They are also very versatile in the laboratory, since their parameters can be adjusted "by the inch.")

The center conductor consists of a fine enameled wire closely spiraled around a polyethylene core. To increase the time delay per unit length, the permeability of the core can be increased by the incorporation of finely divided magnetic materials. In these types, the magnetic losses generally limit the upper frequency to about 5 MHz, which is adequate for most pulse applications.

Pulse Delay Network

The delay characteristics and charging action of RF lines make them useful in some radar applications. They cannot, however, be used in others, chiefly because they would have to be too long. An actual RF line would have to be several hundred feet long for some uses in radar. Even if a line of such length were coiled up, it would occupy more space than is available Thus, so far as airborne equipment is concerned, artificial lines are used instead of actual lines.

Artificial lines possess all the electrical characteristics of actual lines, but do not have the physical bulk. They lump the required L and C values into equivalent inductors and capacitors. The result is an electrically equivalent (but physically different) line. Lumped sections of inductance and capacitance take three configurations: "L," "T," and "π." Of these, the "L" section is the one most commonly used. For this reason, the following explanation will be confined to this type.

In any line, a time interval is required for any voltage change to travel the length of a line. This time characteristic makes it possible to slow down the transfer of a voltage change in its travel from one circuit to another.

The artificial line shown in figure 10-12 provides a means of delaying a pulse voltage 10 microseconds. This line contains an inductance of 0.5 millihenry and a capacity of 0.05μf in each of the two sections. The time for a voltage change to move through one section may be determined from the formula $TD = \sqrt{LC}$. Total delay of the line is $TD = n\sqrt{LC}$ where n is the number of identical line sections.

AT.164

Figure 10-12.–Pulse delay network, simple circuit.

If the individual sections are not identical, time delays can be computed for each section individually, and then added together for the total delay. In most pulse delay networks in actual use, the delay times for each tapped output terminal is stamped on the unit. If necessary, inputs and outputs may be reversed; the computation of the delays between taps is based on the difference between the figures stamped at those points.

Pulse Forming Network

Another characteristic of RF lines is the manner in which the lines charge and discharge when a d-c voltage is applied to them. When d.c. is applied to an open-ended line is which the source impedance is equal to the line impedance, half the source voltage appears instantaneously across the line impedance. The change in voltage travels down the line, charging the line as it goes. When it reaches the open end, it is reflected in phase and starts back along the line. (See fig. 10-13.) All capacitors are charged to half the applied voltage during the trip down, and to full value of the applied voltage during the trip back. When all capacitors have been charged to a value equal to the applied voltage, current stops flowing. On an oscilloscope across the impedance of the source, the wave shape appears as shown in figure 10-13(B). Note that the voltage felt across the impedance of the load is half of the applied voltage during 2TD. At the end of 2TD, the PFN is charged to the full value of the applied voltage and current stops.

When the line is discharged into a resistance equal to its characteristic impedance, the result is a square wave. The wave has a con-

AT.165

Figure 10-13.–Charging a pulse forming network.

stant amplitude, and a duration equal to twice the time for the pulse to travel the length of the line. The amplitude is equal to half the charge voltage because the line discharges through its own impedance and the load impedance (R_L) in series. This cuts the load voltage by half and produces a drop of voltage which immediately travels down the line and back to the starting end, as shown in the illustration in figure 10-14.

As the end of the line is open, the reflection is in phase. This produces a voltage across the load impedance (R_L) equal to half the charge voltage and which lasts for twice the time of one-way travel on the line. Usually, an artificial line is used to generate a square wave. When the L and C are known, the time duration of the square pulse (PW) is equal to

$$PW = 2n\sqrt{LC}$$

When the termination is not equal to the characteristic impedance of the line, discharge cannot be completed in a single round trip. As indicated in figure 10-14 (B), several trips are required for complete discharge of the capacitors. The total number of trips required is dependent on the degree of mismatch between the line and its terminating impedance; the greater the mismatch, the more trips required. An artificial pulse line is capable of producing a perfectly measured square wave pulse with an amplitude of several thousand volts.

Another use of an artificial line is for forming pulses when the receiving end is shorted.

AT.166

Figure 10-14.–Discharging a pulse forming network.

1343

The operation of the line in this case depends on energy stored in the magnetic fields around the inductors in the line. When the voltage is applied to the line as shown in figure 10-15 (A), it moves down the line and charges each capacitor. At the short circuit, the voltage turns around and returns up the line. On its return trip, it discharges all capacitors. Meanwhile, the current also moves down the line and is reflected back at the short. On its return trip up the line, its value is doubled. After one round trip, the voltage across the line at all points is zero, while the current at all inductors is high.

When a load is suddenly connected to the line, the current in the inductors flows through the load. This current drops to half its previous value, proceeds, to the shorted end and back, maintaining a current flow for the time of one round trip through the line.

In many radar systems, the short circuit action is produced by the firing of a thyratron tube. The resulting pulse is then used to trigger the magnetron into operation for a controlled period of time.

IMPEDANCE MATCHING DEVICES

Impedance is a complex characteristic of all a-c circuits. It consists of both resistance and reactance. Every stage, circuit, and unit within the signal path of electronic equipment or system possesses an inherent impedance with respect to the applied signal. The inherent impedance is a characteristic impedance of the functional element concerned. In addition to the inherent impedance, the input and output impedances of the element are important considerations.

The input impedance of a circuit is the impedance presented to a signal at the input to the circuit. It represents a combination of effects on the signal by the circuit and the load connected to its output. The output impedance represents the combined effects of the circuit and

AT.167

Figure 10-15.–Pulse formation, using a shorted line.

its inputs, as felt by the circuit load. These values, as shown in the discussion on transmission lines, may be equal or different.

Impedance matching is the process by which the functional circuit element is coupled to either or both the input and output circuits for optimum transfer of energy. This requires matching not only the resistive component of impedance, but the reactive component as well. For maximum transfer, the resistive components are made equal, but the reactive components are made opposite (but equal in magnitude). Thus for a capacitive reactance of one element, an equal value of inductive reactance must be found in the other.

The calculation of inherent, input, and output impedances is a complicated process beyond the scope of this course. It involves the progressive simplification of series-parallel networks of resistance and reactance components with reflected and distributed properties. Many of the individual values cannot be measured directly. These values must be calculated under varying conditions of frequency and load, including the effects of tube and transistor operation.

Fortunately, however, the technical manuals for many electronic systems and test equipments contain data concerning the input and output impedances recommended for proper matching. Numerous devices are available which have the proper impedances for use in connecting test equipment to units under test. Many technical manuals also contain the specifications and construction details for making impedance matching devices for common applications.

For most common needs, coaxial adapters are supplied as part of newer test sets. This greatly simplifies the impedance matching procedures. As a means of checking the impedance match between physical units, especially at microwave and UHF frequencies, a special class of test equipment, the "slotted line" is provided. This device is used to measure standing waves of voltage on the line, and is usually adjusted for unity standing wave ratio.

CATHODE-RAY CIRCUITS

The circuits used for the electrostatic type of cathode-ray are functionally similar to those used for the electromagnetic type of tube, but differ in the manner of accomplishing their function. Basically, the cathode-ray tube provides a fast moving, easily and quickly deflected electron beam for use in waveform viewing and analysis, and for special display purposes. Generally speaking, the display types of CRT are magnetically controlled, while the types used in test oscilloscopes and synchroscopes (for waveform checking) are electrostatically controlled.

All cathode-ray tubes have basic control circuits which are necessary if the tube is to be used at all. These circuits control intensity (brilliance), focus, and beam positioning (centering, both horizontal and vertical). Other circuits with which the CRT is concerned are horizontal and vertical amplifiers, sweep circuits, and synchronizing circuits. All of the latter are standard circuits, with special attention paid to the design for bandwidth, response, and linearity. In some special cases there are peculiar circuits which are mainly combinations of standard circuits used for packaging the component into a convenient size, and for economy. For example, while a console unit may have high and low voltage supplies, they are usually separate and use separate transformers, whereas the conventional oscilloscope uses one transformer to supply both high and low voltage, bias, and filament power.

FOCUSING METHODS

Three basic focusing systems are used in CRT's, but all three accomplish the same function: they focus the electron beam so that it forms a sharp spot as it impinges on the face of the CRT. The three systems are the permanent magnet, the electrostatic, and the electromagnetic.

The permanent magnet and the electromagnetic systems are identical in effect; they differ only in the manner of producing the magnetic field. A form of electromagnetic focusing is discussed (in connection with klystrons) in chapter 11 of this manual. Although that method is considerably more complex than is normally the case in CRT circuits, the basic action is similar.

The permanent magnet focusing method is usually found in commercial television receivers; it is not in common usage in avionic equipments. Electrostatic focusing is found in

UNIT II - USE OF DRAWING INSTRUMENTS

Compass Lesson 4

OBJECTIVE: To learn to use a compass properly.

RELATED INFORMATION:

FIG. 1

The main function of a compass is to draw circles. To do this properly, set the compass on the scale as shown in Fig. 1 and adjust it to the radius needed; then place the needle point at the center-point on the drawing, guiding it with the left hand (Fig. 2). Raise the fingers to the handle and draw the circle in one sweep, rolling the handle with the thumb and forefinger, inclining the compass slightly in the direction of the line (Fig. 3).

small-screen CRT's used in test oscilloscopes and in the auxiliary indicators of some radar sets.

ELECTROSTATIC DEFLECTION

The following circuits were chosen as basic examples of the circuits generally used in electrostatic CRT's and oscilloscopes. Each was selected to bring out the basic principles and requirements necessary for circuits used in waveform analysis. The discussion is limited to the essentials needed for describing their use with cathode-ray tubes.

Beam-Positioning Circuits

A simple oscilloscope using basic beam-positioning circuits is shown in figure 10-16.

Note that the voltages are taken from a common voltage divider between B-plus and B-minus. The divider is grounded at a convenient point, usually at the positive voltage required for the accelerating anode (A2), and both ends are above ground. With the positive low voltage and negative high voltage at above ground potential, the case and chassis can be grounded for protection of the operator. This system also permits the anode and one of each pair of deflection plates to be grounded, to form a simple unbalanced deflection or positioning circuit. This connection also keeps the deflection plates and accelerating anode at the same potential and avoids defocusing effects from differences in potential between them.

In the balanced positioning circuits (fig. 10-17), each deflecting plate (D1 through D4) is controlled by a separate potentiometer, and the plates are isolated and balanced equally by being connected to the position controls through equal resistors. Each plate is also connected to the deflection amplifiers, through a coupling capacitor, in a push-pull arrangement. Thus the CRT is balanced for d.c., for a.c, and for any stray capacitance to ground. Since the isolating resistors (R1, R4, R5, and R8) are always of a very large value, the deflecting plates may be connected into any circuit without danger to the operator. (It takes a current of only a few microamperes to drop the positioning voltage to zero).

Sweep Circuit

To provide a time base for the waveform, the CRT beam must be deflected horizontally across the face of the tube from left to right, then caused to return quickly from right to left, ready to resume another cycle of operation.

Some oscilloscopes provide blanking for the retrace period so that the return sweep cannot be seen. A typical thyratron type sweep generator for general oscilloscope use is illustrated and explained in Basic Electronics.

AT.168

Figure 10-16.–Simplified schematic of basic oscilloscope.

AT.169

Figure 10-17.–Balanced positioning circuit.

13440

Other types of relaxation oscillators, such as a neon tube, a vacuum tube RC oscillator with discharge tube, or a multivibrator, could be used, provided that a reasonably linear sawtooth sweep waveform is produced.

Synchronizing Methods

To keep the waveform stationary on the face of the CRT, the sweep frequency must be an exact multiple or submultiple of the waveform under observation. To avoid the need for constant resetting of the sweep frequency control (because of drift, power supply voltage changes, etc.) a sweep-locking or synchronizing circuit is provided.

Since some circuits do not have an output of the proper polarity for synchronization, an adjustable synchronizing circuit is sometimes included to permit selection of sync signal and choice of sync polarity. Figure 10-18 shows a typical sync input circuit of this type. Switch S1 selects one of three inputs: an external synchronizing signal, a 60-hertz signal (usually taken from a filament winding), or the output from the vertical amplifier (this is the signal under observation, but it is called internal sync). It then applies the input through coupling capacitor C1 to the grid of V1.

Tube V1 is a paraphase amplifier, with the grid returned to ground through R1. The tube is cathode-biased and unbypassed; the plate and cathode resistors (R2 and R3) are of the same value, so that for the same current identical signals are developed in the plate and cathode circuits (except of opposite polarity). For a positive input signal, a negative plate output signal is developed, and the cathode output signal is positive. For a negative input signal, a positive plate output signal is developed, and the cathode is negative. Both plate and cathode outputs are coupled (through capacitors C2 and C3) to a common variable load resistor, grounded at a center tap. At the ground position, both signals are of zero amplitude; therefore, no output is obtained.

Figure 10-18.–Typical sync input circuit.

As R4 is rotated in either direction, the signal amplitude is increased. Since the synchronizing signal to the sweep generator must be of positive polarity, for a negative input to V1 a positive signal is available on the plate side, and for a positive input to V1 a positive signal is available on the cathode side. Thus a signal similar to the input signal but of positive polarity is obtained and coupled through C4 to the sweep generator.

When the sweep generator is adjusted to a slightly lower frequency than that desired, a positive-going sync signal is applied to the grid, the sweep generator locks in and operates at the same frequency as the sync signal. Thus the CRT waveform remains stationary, rather than drifting across the screen, because it is synchronized so that the sweep occurs at the same place (at the same time) each sweep.

To produce satisfactory deflection with small signals, it is necessary to employ both vertical and horizontal deflection amplifiers. These stages may be single-ended or push-pull (unbalanced or balanced); they are conventional video amplifiers designed for the desired frequency response and linearity. The horizontal amplifier in a good scope is identical to the vertical amplifier, permitting the same signal to be applied to the X (horizontal) axis or to the Y (vertical) axis.

Attenuators

Since the vertical amplifier must be able to amplify very weak signals with sharply rising waveforms, it must have good frequency response and large amplification. To cover the range of signal amplitudes encountered, the vertical input is usually provided with an at-

13441

tenuator. Three types of attenuators are shown in figure 10-19.

The simple circuit shown in (A) uses a potentiometer as the output load resistor of an RC coupling network. The grid-to-ground impedance of the input tube is in shunt across the lower portion of the potentiometer and in series with the upper portion. As the potentiometer arm is moved upward, the impedance presented to the circuit under test is decreased. This results in less attenuation of the signal and less loading of the circuit.

(A) POTENTIOMETER

(B) STEP POTENTIOMETER

(C) FREQUENCY COMPENSATED STEP

AT.171

Figure 10-19.–Attenuators.

The simple step attenuator circuit shown in (B) is a better type of input circuit, allowing coarse selection of the attenuation ratio with switch S1, and fine adjustment with potentiometer R3. Even for the smallest input step resistance, the full range of R3 is available for control. With the available settings of S1, the input impendance will never decrease to a value less than the series section of R2 (that portion above the upper tap) plus the parallel combination of the remainder of R2, R3, and the grid-to-ground impedance of the input tube.

The most desirable input impedance is in the range of megohms, with little or no shunting capacitance to ground. To achieve this result, a cathode follower input stage is sometimes combined with a step attenuator to isolate the oscilloscope input from the stage being tested.

Frequency compensated attenuators are used in the better type of oscilloscopes to minimize the effect of input capitance (fig.10-19 (C)) by presenting identical impedance response curves to the circuit under test for the various attenuator settings.

Frequency compensated attenuators provide the same voltage division ratio to resistive and reactive components of the input signal, so that the drop in signal level at the higher frequencies can be compensated in the video amplifiers. Attenuator compensation is usually effective over the entire useful frequency range of the oscilloscope.

Most attenuators and amplifiers have reduced high frequency response because of the shunting effect of stray capacitance. A parallel RC circuit is usually inserted in series with the input lead to boost the relative response of the attenuator at high frequencies. Another device is an input probe located at the end of a special connecting cable which applies the input to the vertical amplifier. The probe houses a frequency compensated voltage divider, to reduce the amount of shunt capacitance at its input terminals. This is usually called a DC probe (or simply input probe), as distinguished from an

13442

RF probe which contains a diode rectifier to remove the modulation.

Signal Amplifier

A typical three stage signal amplifier is shown schematically in figure 10-20; it drives a conventional push-pull paraphase deflection output amplifier. The input signal is applied through blocking and coupling capacitor C1 to a cathode follower attenuator stage incorporating triode V1. The attenuator is a two step, frequency compensated type.

Y-gain (vertical) control R6 controls the amplitude of the input signal to the video amplifier consisting of V2 and V3. Both high frequency and low frequency compensation are employed in each stage. The cathode of V2 is bypassed by a small capacitor, which makes it degenerative for low frequencies, thus reducing the response and flattening out the low frequency response. The high frequency response is increased by peaking coils L1 and L2 (which compensate for the shunting effect of tube and wiring capacitance and provide a reactance which increases with frequency).

Amplifier V3 is fixed-biased by connecting the cathode to the junction of R13 and R14, which are connected in series between the plate supply and ground. Cathode resistor R14 is also unbypassed so that the circuit is completely degenerative for high and low frequencies, further improving the overall frequency response. The use of the fixed cathode bias sets the operating point of V3 and helps stabilize the stage.

An output from the cathode of V3 is taken for application to the sync circuit for internal synchronization. The main output of V3 is fed to cathode follower output stage V4, which is biased positive with respect to ground by plate current, even though the cathode is returned to the minus supply. Variable potentiometer R16 serves as output control to adjust the signal amplitude for application to a paraphase amplifier.

AT.172

Figure 10-20.–Three-stage signal amplifier.

13443

Deflection Amplifier

A common type of deflection amplifier used for electrostatic deflection is the paraphase amplifier, shown in figure 10-21. In this type of circuit, a balanced output is obtained from a single ended input signal by means of common coupling in the cathode circuit of both tubes. (The circuit is known as a cathode-coupled paraphase amplifier.)

The input signal, shown as a positive pulse, is applied to the grid of V1, with the grid returned to ground through R1. Cathode bias is obtained by means of R2, which is common to both V1 and V2. Since R2 is unbypassed, the input signal at the grid of V1 also appears at the cathode, while the inverted signal appears at the plate as one output of the circuit. The signal at the cathode of V1 is applied, through direct connection to the cathode of V2.

The grid of V2 is connected to a balance potentiometer which acts as a voltage divider between E_{bb} and ground. Thus the output signal of V2 can be adjusted to equal that of V1. The positive pulse at the cathode of V2 increases the bias, decreases the plate current, and produces a positive output at the plate of V2. The plate output signal of V2 is reversed in polarity from the input signal, as in any ordinary vacuum tube amplifier.

The input to V2 is the signal voltage developed across R2. This signal is applied to the cathode of V2 (which has its grid returned to ground through R5 and is thereby at ground potential to the signal). Therefore, the output signal at the plate of V2 has the same polarity as the input signal at the cathode of V2 or the input signal at the grid of V1. In this way, the output signals from the plates of V1 and V2, which are applied to the deflection plates of the CRT, are equal in amplitude but opposite in polarity (phase).

The circuit operation and the schematics given above have, for simplicity, omitted the additional compensation networks which are often included in specific applications. In order that deflection amplifiers do not restrict the bandwidth of the input signal, they must have wide frequency response, low distortion, and time delay proportional to frequency, similar to the characteristics of video amplifiers.

ELECTROMAGNETIC DEFLECTION

When a very large screen is used and correspondingly large deflections are required, it is not practical to use electrostatic deflection. The extent of deflection desired would require greater spacing between the deflection plates and, consequently, unusually high signal voltages would be necessary. It is simpler to obtain large deflections in a relatively short tube by means of magnetic fields. In addition, with magnetic deflection, it is easier to obtain the special types of sweep required by radar PPI, scanning sonar, and television picture tubes.

It should be noted that both the electrostatic and electromagnetic deflection systems have their advantages and disadvantages. The electrostatic deflection systems are used when high sweep frequencies are needed. The electromagnetic systems have the disadvantages of frequency limitations and high weight and large size.

The common method of obtaining electromagnetic deflection is to use two pairs of electromagnets around the neck of the CRT. This simplifies the construction of the tube since no internal deflection plates are required and focusing is also accomplished electromagnetically. Instead of applying a signal voltage across deflection plates, the final signal amplifier tubes send a strong signal current through the electromagnets. The amount of current varies to follow the signal that is being examined, and thus the electron beam deflection is proportional to the signal.

Trapezoidal Input

Figure 10-22 illustrates a simplified typical deflection amplifier for producing a horizontal time base using magnetic deflection. The input signal is a trapezoidal waveform of voltage as shown in the illustration.

The input is applied through coupling capacitor C1 to the grid of V1, which is operated as a Class A stage with fixed bias. Sufficient negative bias is applied to prevent the grid from going positive with maximum signal input. V1 is a pentode or a beam power type, in order to obtain the power amplification required to furnish current to the deflection coil (This coil may require between 50 and 100 milliamperes of current for maximum beam deflection.)

The output of V1 is applied to the deflection coil, which in the illustration is represented by an inductance, L1, with a resistance, R2, in series with it. R2 is shown as a dotted resistance because it is actually a part of L1. The output voltage waveform at the plate of V1 is trapezoidal; when this waveform is applied to the series R-L circuit (deflection coil), the voltage waveform appearing across the resistance is resolved to a sawtooth shape, while that appearing across the inductance is resolved to a square-wave shape.

The square wave of voltage across the inductance causes a sawtooth wave of current through it, which is the required waveform for producing a horizontal time base deflection on the screen of the cathode-ray tube. The development of the sawtooth current waveform from the trapezoidal voltage input waveform is shown in figure 10-23.

The trapezoidal voltage input waveform to the grid of amplifier V1 is shown in (A); the differentiated voltage which appears across the inductance is shown at (B); the integrated voltage which appears across the resistance (of the coil) is shown at (C); the current through the deflection coil, which is the composite result of waveforms (B) plus (C) is shown at (D).

Square Wave Input

The input signal to the amplifier (shown in fig. 10-24 (A) is a square wave, instead of the trapezoidal wave required in the previous circuit. This signal is applied to the grid of V1. The grid is returned to ground through resistor R1. The positive voltage applied to the cathode of V1 (from the plate supply by means of the voltage divider action of R3 and R2) maintains V1 biased to cutoff in the absence of an input signal.

When the first positive pulse of the input square wave reaches the grid, the tube conducts heavily. The resulting plate current, flowing through deflection coil L2 and inductor L1, rises exponetially toward a value which would be limited only by the resistance of the circuit. Before this limiting point is reached, however, conduction of the tube is suddenly interrupted by the negative going end of the square wave input pulse. In this way, only a relatively linear portion of the exponentially rising waveform is utilized.

AT.174

Figure 10-22.–Electromagnetic deflection amplifier.

When the conduction of the tube is interrupted at the end of the positive square wave, V1 is cut off, and the current decays rapidly to zero. This rapid decay is due to a change in the time constant of the circuit between the rise and fall of the current.

During the rise of current, the circuit time constant (L/R) is long. The resistance is composed of cathode resistor R2 and the low value of plate resistance of V1. During the decay of current, the time constant is made short, as a result of the increase in the value of plate resistance when V1 stops conducting. With the shortened time constant, the current decays rapidly.

The sudden decay in current flowing in the deflection coils when the tube stops conducting causes a counter emf in the coil, which opposes the current decay. In addition, the circuit may be shock excited into oscillation by the sudden change in value of current. Although the oscillations gradually die out, they may continue into the following sweep, especially if the circuit Q is high. This condition may result in a nonlinear start of the buildup of current in the coil, and therefore a nonlinear sweep, as shown in figure 10-24 (B).

These oscillations can be eliminated, or damped out, by lowering the Q of the circuit by means of a resistor shunted across the coil. This wastes some of the deflection current, however. A more satisfactory method incorporates the use of a damping diode shunted across the deflection coil, as shown in figure 10-24 (C), where diode V2 acts to damp out the oscillation.

The current through V1 is increasing during the rise of the sawtooth current wave shown in (B), to provide the sweep deflection. The voltage at the plate of V1 is lower than the plate supply voltage by the amount of voltage drop in the deflection coil and inductor. The cathode of damping diode V2 is therefore more positive than its plate, and the diode will not conduct.

When the current through V1 falls to zero at the end of the sawtooth current wave, the voltage at the plate tends to rise above the plate supply voltage due to the fact that the cemf (generated by the inductance) adds to the plate supply voltage. When this condition is reached, damping diode V2 conducts, and any oscillations are dissipated in resistor R5.

Balanced output (push-pull) circuits, when used, usually operate by means of a phase inverter circuit fed from a single ended source. In some radar deflection circuitry, the two outputs obtained by means of a phase inverter are separately amplified by individual single ended deflection amplifiers, and then applied to the two separate windings of a split winding deflection yoke.

CONTROL CIRCUITS

This discussion will cover some of the commonly used circuits which control the voltage gain of an amplifier stage or control the frequency of a local oscillator stage.

AGC AND AVC SYSTEMS

In common electronics usage, the terms "automatic gain control" (AGC) and "automatic volume control" (AVC) are used almost interchangeably. Technically, however, AVC is properly applied only to circuits whose ultimate output is an audible signal. AGC is a broader term which includes audible signals and inaudible signals of all varieties. The circuit itself provides a means of automatically controlling the output of an amplifier, by regulating the gain in accordance with the strength of the input signal. Since the same basic circuit is used for both the audible and the inaudible signal, this discussion will use the term AGC in all applications.

In most circuits controlled by AGC voltages, remote cutoff amplifiers are used. Before proceeding with the discussion of AGC systems, a

brief review of the characteristics of a remote cutoff pentode is presented.

Remote Cutoff Pentode

Figure 10-25 shows the E_c/I_b characteristic curve for a typical remote cutoff pentode used as an RF or IF amplifier, and the effect on plate current variations caused by changes in control grid bias.

When the signal input to the tube is small (e_g1), the developed voltage is low and the plate current variation (i_p1) is centered about point A. When the signal input to the receiver is large (e_g2), the developed voltage increases and the plate current variation (i_p2) is centered about point B. The plate current variation resulting from a small input and the plate current variation resulting from a large signal input are approximately equal, in theory; this should produce output signals of approximately the same amplitude.

Although the relationships given in the illustration are idealized, they serve to show the effect of applying a negative control voltage to an amplifier stage. In actual practice, it is necessary to supply the AGC voltage to several

AT.177

Figure 10-25.–Remote cutoff pentode E_c/I_b curve.

effect of applying a negative control voltage to an amplifier stage. In actual practice, it is necessary to supply the AGC voltage to several remote cutoff amplifier stages simultaneously in order that the cumulative effect will produce a satisfactory control of signal amplification by the controlled stages.

Circuits vary somewhat because of the overall gain characteristics required of the receiving system. However, most AGC circuits fall into one of three general classifications: simple AGC, delayed AGC, and amplified and delayed AGC. These three classifications of AGC circuits are described briefly in the paragraphs which follow.

Simple AGC

A simple AGC circuit and a diode detector circuit are very similar in many respects. For this reason, the AGC circuit and the signal detector circuit of a receiving system are frequently combined within a single stage. Figure 10-26 illustrates a simple AGC system. This system makes use of a negative d-c control voltage obtained directly from the signal detector output, since the rectified voltage produced by the detector is proportional to the amplitude of the received carrier.
